*To
David G. Simons (June 7, 1922-April 5, 2010)
and*

Lois S. Simons (March 6, 1934-July 3, 2004), whose guiding spirits are ever with us.

This third edition of *The Trigger Point Manual* has been a labor of love and is dedicated to the memory of David G. Simons, who devoted his post-military medical career to advancing myofascial pain and trigger point scientific and clinical research. His passion, commitment, and dedication to expanding the scientific body of knowledge of muscle pain in order to help decrease the pain and suffering of human beings was unparalleled.

David G. Simons was a true pioneer, both as one of the most highly respected scientists in the field of myofascial pain and in the treatment of patients with chronic pain. His wife and coauthor, Lois S. Simons, used her expertise in muscle anatomy and kinesiology as well as her outstanding clinical skills to build on the solid physician-oriented clinical foundation laid by Janet G. Travell (1901-1997) in the first edition.

For those of us who knew David and Lois, we have tried to respect their goals for this third edition and are pleased to have had the opportunity to complete the task they were unable to finish.

Foreword

The publication of Travell & Simons' first volume of *Myofascial Pain and Dysfunction: The Trigger Point Manual*, in 1982, followed 10 years later by the second volume, and in 1999 the second edition of volume one, created a revolution in the understanding and management of musculoskeletal pain, but also caused an eruption of critical comments of volcanic proportions. The revolution amounted to a new way of looking at musculoskeletal pain via the concept of the myofascial trigger point, a concept introduced and expanded upon over the preceding three decades by Dr Janet G. Travell, later joined by Dr David G. Simons, but never before presented in a comprehensive text. Travell's unique insight that was detailed in the first volume was the appreciation that muscle pain could present as pain referred to a distant site. Referred pain, now known to be mediated through the central nervous system and associated with visceral organs and joints as well as with muscle, was neither well understood at the time nor widely accepted. Moreover, Dr Travell identified the myofascial trigger point as the cause of local pain in muscle and the cause of pain referred to distant sites. She identified the trigger point on physical examination by manual palpation. There was no objective way to identify the trigger point by laboratory test, for example, by imaging or by electrodiagnostic examination. The idea that pain could be referred from one place to another was ridiculed at national medical meetings and dismissed as fantastical thinking. The storm that Travell created was largely due to the inability of the mainstream medical profession to understand the concept of referred pain from muscle, coupled with an inability to examine muscle as carefully and as well as she could. Lacking in the texts by Travell and Simons, however, was a critical, evidence-based approach to the descriptions of trigger point pain and their referred pain patterns. Dr Travell's description of referred pain patterns was based on decades of meticulous record-keeping of patient's reports and the drawings that Dr Travell made of her patient's descriptions of their pain, but all of her descriptions were qualitative, not quantitative. Neither was the science of pain medicine advanced enough to understand referred pain. The pathophysiology of peripheral and central pain mechanisms had barely begun to be revealed by the time the single volume of the second edition appeared in 1999, and objective markers of the myofascial trigger point were only starting to appear, most notably an electrophysiologic change in the muscle of the trigger point that is now called endplate noise. Even that was controversial for decades, claimed by many to be nothing more than normal endplate electrical activity. Despite these shortcomings, the texts by Travell and Simons were eagerly read by those who treated musculoskeletal pain. With the passage of time, and more knowledge of the pathophysiology of muscle pain, the texts achieved an iconic status.

Almost 20 years have passed since the publication of the last edition of *Myofascial Pain*

and Dysfunction: The Trigger Point Manual, 2nd edition, and medicine has advanced and changed greatly since then. Much more is known about the development of pain, about peripheral and central sensitization as it applies to muscle, with major contributions by Siegfried Mense and his colleagues, and central pain modulation is now an accepted phenomenon, thanks to the work of David Yarnitsky and others. Nociception is now understood to be a complex matter involving integration of multimodal sensory input, interconnectedness of cerebral centers, and functional coordination with the motor system. Furthermore, much more is known about myofascial trigger point anatomy and physiology through the studies using microdialysis analysis of the trigger point milieu performed at the National Institutes of Health by Jay Shah and his associates, the ultrasound appearance of the trigger point that has been detailed by Sikdar and his colleagues in Northern Virginia, and the work done by Hubbard and his associates, and Hong and his colleagues on the electrodiagnostic features of the trigger point. The importance of fascia in pain of myofascial origin is undergoing its own revolution. Knowledge of fascial anatomy and physiology is rapidly increasing, though how fascia and muscle interact to produce pain is still not well explicated. In addition, and most importantly, medicine has moved progressively toward an evidence-based, scientifically supported, practice, rather than so much an art that we used to emphasize, although this is not to denigrate the role of history and physical examination in defining a patient's pain problem. There is still a need for an educated, intuitive evaluation of the patient that we call the art of medicine, both in diagnosis and in treatment. It is at this time of great change and expansion of knowledge that this new edition of *Myofascial Pain and Dysfunction: The Trigger Point Manual* appears.

The present volume, the third edition of Simons, Travell, and Simons' text, brings the previous editions of this popular resource up to date. It is an evidence-based text where evidence is available. The references to muscle function and anatomy are updated. The initial chapters in the text are a general introduction to myofascial pain, written by Jan Dommerholt, who is both clinically well acquainted with myofascial pain syndromes and extremely well versed in the current literature, having authored regular reviews of the literature in this field for over a decade. Dommerholt provides the background of pain science, reviews what is currently known about the trigger point, and provides the basis for a proper understanding of the later chapters that detail diagnosis and treatment of particular muscle trigger points and of regional trigger point syndromes. He has also introduced for the first time in this text a detailed discussion of the anatomy and of the role of the fascia in myofascial pain. Of great importance is that the treatment modalities used in the management of myofascial pain that are described in the text, most importantly the technique of dry needling, are supported by the citation of randomized, controlled trials and by systematic reviews and meta-analyses. Gone are the detailed instructions of spray and stretch in favor of dry needling as a treatment of trigger points. In keeping with David Simons' inquisitive mind and drive to understand what underlies myofascial trigger points, a chapter is included that expands on Simons' Integrated Hypothesis of the Trigger Point and presents new and novel hypotheses about the origin of the trigger point, but based on firm evidence of trigger point characteristics. Likewise, a chapter on perpetuating factors is

included in recognition of treatment of a trigger point as being the beginning of management of myofascial pain syndromes, not the end. The chapter on perpetuating factors includes material that was not included in previous editions, such as gonadal hormone and sex effects on pain, and integrated postural considerations involving motor control.

The text has, of necessity, many contributing authors. In this respect, it differs greatly from the first two editions, which spoke in the unique voices of Janet G. Travell and David G. Simons, with only six additional contributors in the second edition. In the previous editions, one can hear Travell's admonitions and gems regarding the patient's history that truly expressed the art of medicine, while Simons' voice was grounded meticulously in the scientific literature. This volume, written by many authors, maintains a consistent approach as each chapter about a specific muscle follows a similar format that includes anatomy, function, pain presentation, referred pain patterns, and perpetuating factors and conditions that are specific to a given muscle. The detailed reviews of the literature regarding these topics is left to the previous volumes, perhaps out of the recognition that a single volume of 77 chapters would otherwise become too unwieldy. The presence of many contributors means that each chapter reflects the interest and voice of the author(s) of that chapter. The chapters by César Fernández de las Peñas and Orlando Mayoral del Moral are models of detailed and well-documented discussions of their subjects, for example, which is not to say that others do not also achieve their level of distinction. The editors and publishers have elected to keep the illustrations made by Barbara Cummings from the previous editions, a wise choice as they were made in close consultation with David G. Simons, who went to the anatomy laboratory in order to ensure accuracy in the illustrations. These illustrations are unequaled in their clarity and usefulness. Moreover, the X's that Travell and Simons added, to signify the major sites in each muscle where trigger points can be found, have been removed from the figures in recognition of the fact that trigger points can be found elsewhere in the muscle, and the muscle must be systematically examined. It must be said, however, in recognition of the need to keep this volume to a usable size and affordable cost, that the previous editions of this text should be kept on the shelf as a reference for the greater detail of description that the previous format permitted, as well as for the unique voice of its authors, which is not found in this edition.

Finally, recognition and thanks must be given to Joseph M. Donnelly, who gamely undertook this rather daunting project. David G. Simons had planned to edit a third edition himself, but was unable to do so during his lifetime. Donnelly accepted the arduous work of assembling a team of associate editors and a stable of writers, wringing the chapters out of them, writing chapters himself, shepherding the project with all of the delays, procrastination, and frustrations associated with such a project, and doing so for the first time in his career. This project has been an arduous task, one that I hope will be recognized as a labor of love, for the welfare of all of our patients everywhere, but most importantly for the love of David G. Simons, a man who taught us, cajoled us, nursed us, urged us to think clearly, and who was indeed responsible for getting the first two editions published. It is truly in gratitude to David G. Simons, and to Janet G. Travell, that Joe Donnelly and all of

us associated with this project have worked together to produce this text, which we hope will serve as an indispensable guide for the next generation of myofascial pain practitioners.

Robert D. Gerwin, MD, FAAN

Preface

This third edition of *The Trigger Point Manual* is presented at a time of exponential growth of knowledge, rapid advancements in technology, immediate access to information, and constant change. As each professional is required to learn more and more to practice in smaller and smaller specialties, we can only cope by collaborating with others whose expertise lies in adjacent fields of knowledge. This new edition of *The Trigger Point Manual* has evolved to meet the needs of this environment. Dr Janet G. Travell authored Volume I of the first edition of *The Trigger Point Manual*, which David G. Simons wrote for and with her. In turn, informed by his Veteran's Administration clinical experience, he authored and wrote practically all of Volume II with significant help from Lois S. Simons. The second edition of Volume I was truly coauthored by David G. Simons and Lois S. Simons with significant help from clinicians in multiple disciplines. This third edition is the combined effort of many more people, each representing expertise in one or more of the many aspects of myofascial pain and trigger points (TrPs).

This third edition of *The Trigger Point Manual* is a transitional work. It continues the discussion of the TrP conceptual model that took form out of a syndrome of unknown etiology and then evolved into an experimentally established neurophysiologic disease entity. Improvements in technology have enabled the empirical identification of signs of myofascial pain and dysfunction, including electrophysiologic markers formerly known as "endplate noise," which was first established by David G. Simons; histopathophysiologic markers such as contractures of sarcomeres; and histochemical changes such as decreased pH and elevated levels of neuropeptides and cytokines. There have been significant scientific advancements in regard to TrPs and myofascial pain since the second edition of Volume I was published in 1999; however, many important details remain to be resolved in regard to the TrP conceptual model. This third edition aims to be not the final answer to the questions that remain regarding myofascial dysfunction and TrPs, but, instead, like the seminal works that preceded it, another touchstone to mark a new era of discovery.

CHANGES IN THIS EDITION

In alignment with the vision of David G. Simons and Lois S. Simons, the third edition of *The Trigger Point Manual* evolved from a two-volume reference text written mainly by two individuals to a singular volume written by numerous individuals with clinical expertise in the examination and treatment of myofascial pain and dysfunction. This is a multidisciplinary effort aimed at presenting the depth and breadth of TrPs and myofascial pain concepts. This edition presents the major progress made in our understanding of the pathophysiologic basis for many of the clinical phenomena associated with TrPs, including the role of muscle pain and TrPs in peripheral nociceptive drive to the central nervous

system, as well as the role that TrPs play in perpetuating peripheral and/or central sensitization. This text is an evidence-informed review based on clinical and scientific research.

The book is organized into eight sections. The first section introduces the TrP conceptual model and general concepts related to pain and myofascial dysfunction. Psychosocial considerations in myofascial pain syndrome and chronic pain are discussed in Chapter 5 of the first section of the book. Each muscle or muscle group is considered in Sections 2 to 7. A major change to these sections was the merging of the lower torso pain section from Volume II with the upper torso pain section from Volume I to create a new section called “Trunk and Pelvic Pain.” Other changes include merging of the pectineus muscle chapter into the chapter that addresses the adductor muscle group, pulling the tensor fasciae latae muscle into the gluteus minimus muscle chapter, adding the sartorius muscles to the quadriceps muscle group chapter, and combining the superficial and deep foot intrinsic muscle chapters to better reflect current anatomical organizational concepts of the foot. Also new in Sections 2 to 7 is a Clinical Considerations chapter for each section that discusses myofascial factors relevant to common neuromusculoskeletal and medical conditions of each region from a holistic perspective. Section 8 of the book presents a comprehensive summary of treatment options for muscle dysfunction and TrPs. Deviating from the previous editions’ redundant and cumbersome treatment discussions placed within each muscle chapter, this edition gives an overview of each treatment option that can be applied to any muscle in the body with TrPs or in patients presenting with myofascial pain syndrome. The treatment section includes chapters on injection/dry needling, manual therapy, therapeutic exercise, therapeutic modalities, and postural and footwear considerations.

Each of the muscle chapters in Sections 2 to 7 is consistently organized throughout the book with the following sections and subsections: Introduction; Anatomical Considerations, which includes Innervation and Vascularization, Function, and the Functional Unit; Clinical Considerations, which includes Referred Pain Pattern, Symptoms, Patient Examination, and Trigger Point Examination; Differential Diagnosis, including Activation and Perpetuation of Trigger Points, Associated Trigger Points, and Associated Pathology; and Corrective Actions. This new layout includes both clinician-centric and patient-friendly additions as well as a streamlined look for ease of use.

Several new features within the new organizational layout merit note. The introduction of each chapter serves as an overview of all the sections that follow it as an abstract does for the journal articles that have become the staple of research consumption. Vascularization, which was previously omitted, has been included in the anatomical section along with innervation. The new tabular format of the functional unit allows for easier clinical application with additional functional relationships noted in the text below the functional unit boxes. The corrective actions section is written in patient-friendly language and gives the layperson simple self-treatment techniques, as well as signs that warrant seeking professional guidance.

Some changes are reflected in the above organizational theme, but owing to their

substantive nature, require further explanation. One such change is replacement of the terms “satellite” and “secondary” TrPs with “associated” TrP (discussed in each muscle chapter in the Differential Diagnosis section, under the subsection titled “Associated Trigger Points”) to more accurately describe pathophysiologic relationships between TrPs. To enhance this edition’s focus on muscle dysfunction and TrPs, discussions of articular dysfunctions, postural deviations, bony alignment issues, and other related musculoskeletal concerns that were lengthy in the previous editions have been truncated. With widespread availability of and access to comprehensive resources on the examination and treatment of articular dysfunctions and the like, clinicians are encouraged to seek out other texts for more information on those topics.

Trigger point palpation techniques for each muscle, as well as some examination techniques and special tests, are presented with new full-color digital photographs to give the entire text a more modern feel, while the classic anatomy and pain pattern illustrations have been preserved and updated. Lastly, and of special importance, this edition eliminates the “X’s” from the illustrations of referred symptom (pain) patterns. Current evidence supports the need to examine the entire muscle for the presence of a taut band, spot tenderness, and referred symptoms (pain) in order to diagnose the presence of TrPs. It is also known that these referred symptom illustrations are guidelines and that any portion of the muscle can create all or part of the featured referred symptom (pain) patterns.

The third edition of *The Trigger Point Manual* is a testament to the groundbreaking work of Janet G. Travell, David G. Simons, and Lois S. Simons in the realm of TrPs and myofascial pain. This comprehensive *Trigger Point Manual* was designed and written with the patients we serve at the forefront of every decision. The intent of this edition of *The Trigger Point Manual* is to facilitate practice, support education, and inspire clinical and scientific research in the area of TrPs, myofascial pain, and other musculoskeletal syndromal diagnoses. This *Trigger Point Manual* is also designed to assist clinicians with clinical decision making and with the management of patients and individuals presenting with painful and nonpainful conditions resulting in activity limitations and participation restrictions.

Acknowledgments

The editors would like to thank all of the contributing authors of this third edition of *The Trigger Point Manual*. This book was a massive project and could not have been completed without their passion, dedication, and commitment. We appreciate the time they took out of their busy clinical, teaching, and research schedules, and we are indebted to these individuals for sharing their expertise in the area of TrPs and myofascial pain. Special thanks to Jan Dommerholt for his significant clinical and research contributions in the area of TrPs and myofascial pain syndrome. His vast knowledge of the scientific and clinical evidence is apparent in his evidence-informed review in Section 1. Thanks also to John Lyftogt, MD for his input on use of dextrose in the treatment of myofascial pain and to Blair Green, PT for her contribution to the pelvic floor section of the trigger point injection (TrPI) and dry needling (DN) material. Lastly, many thanks to Shantel Phillips, PT for helping confirm postural deviations for Chapter 076.

This book represents years of planning and dedicated effort, and it could not have been finished without the assistance of Sharon Barker and Samantha Pierce. Their rich historical perspective and administrative experience from working with David G. Simons, MD and Lois S. Simons PT was pivotal in achieving the goals of this new edition.

We also want to thank Susan and Norris Ganstrom and the Simons family for their support and encouragement to finish the work their father had set out to accomplish prior to his passing. Thanks to Carolyn McMakin, DC who had the foresight to push the initiative forward with the publisher and wisdom to keep the ball rolling so the project would finally be set in motion.

We would like to thank Christynne Helfrich, PT for her willingness to be our photographer for the entire project. Her clinical expertise and her optimistic perspective made photo shoots seamless and enjoyable. To all the Mercer University Doctor of Physical Therapy students (and their loved ones) who modeled for the photo shoots on Saturdays, we thank you for your enthusiasm and patience. Additionally, we would like to thank Cody Klein, Taylor Smith, Tom Christ, and Rebecca Goldberg, our graduate research assistants, who performed countless literature searches and organizational tasks, always with a smile.

The Editor in Chief, Joseph M. Donnelly, would like to personally thank Leslie F. Taylor, PT, PhD, Associate Dean at Mercer University, for her unwavering support and contributions to the third edition of *The Trigger Point Manual*. I also want to thank my faculty colleagues and staff for their support and encouragement over the past four years. Without their commitment and dedication to teaching and scholarship, this project would never have been completed.

Finally, we would like to acknowledge the support of our respective families and friends. We thank them for their continued support of our professional endeavors and owe

them an incalculable debt of gratitude. May this book be a valuable resource for clinicians and patients, worthy of their sacrifice.

Introduction to Myofascial Pain and Dysfunction

Pain Sciences and Myofascial Pain

Jan Dommerholt, Robert D. Gerwin, and Carol A. Courtney

1. INTRODUCTION

Chronic or persistent pain conditions are the most common cause of disability at an annual cost greater than \$650 billion in healthcare and lost employment in the United States alone.¹ The economic costs associated with chronic pain outpace the combined costs from diabetes, cancer, and heart disease. Chronic pain leads to more deaths than motor vehicle accidents. In spite of the staggering economic costs and overwhelming personal impact, there are few efforts to prevent chronic (persistent) pain conditions and to develop evidence-informed management strategies.²

Chronic (persistent) pain is often defined as pain lasting for more than 3 or 6 months, but length of time as the main criterion is not based on any specific mechanism that separates acute from chronic pain. Reichling et al proposed that there are at least two distinct types of chronic pain.³ Type I is acute pain that persists for a prolonged period of time, whereas Type II involves a mechanistic transition from acute to chronic, involving the disconnection of the generation of pain by the initial tissue injury, or the loss of responsiveness to therapies that are successful for acute pain. Myofascial pain takes a prominent place in the spectrum of acute and chronic pain syndromes. In the original volumes of the Trigger Point Manual, Travell and Simons maintained that most people will experience painful myofascial trigger points (TrPs) at one time or another.^{4,5} Recent prevalence and incidence studies have confirmed that TrPs are indeed very common in a wide variety of conditions.^{6–22}

Myofascial pain, unfortunately, is often overlooked as a potential contributing or causative factor to other pain problems.²³ Trigger points commonly constitute a primary dysfunction, and they may occur in the absence of any underlying medical condition or tissue damage.²⁴ As such, TrPs can function as sources of persistent peripheral nociceptive input independent of tissue damage.^{25–27} They can be associated with other conditions such as whiplash injuries or osteoarthritis.^{8,28,29} Trigger points in the upper trapezius correlate with cervical spine dysfunction at the C3 and C4 segmental levels without

necessarily having a causal relationship.³⁰ A single spinal manipulation induced changes in pressure pain sensitivity in latent TrPs in the upper trapezius muscle.³¹ Trigger points may compound the symptoms of other conditions and persist long after the original initiating condition has been resolved. They can be associated with visceral conditions and dysfunctions, including endometriosis, interstitial cystitis, irritable bowel syndrome, dysmenorrhea, and prostatitis.^{32–39} Myofascial pain can mimic other pain diagnoses such as neuropathic pain, complex regional pain syndrome, systemic diseases, tinnitus, and certain metabolic, parasitic, and nutritional disorders, among others.^{40–48} Although different definitions of TrPs are used among different disciplines, the most commonly accepted definition maintains that “a TrP is a hyperirritable spot in a taut band of a skeletal muscle that is painful on compression, stretch, overload or contraction of the tissue which usually responds with a referred pain that is perceived distant from the spot.”⁴⁹ Although Travell and Simons distinguished different types of TrPs, including active, latent, satellite, and primary and secondary TrPs, in the current thinking, only active and latent TrPs are considered in research and clinical practice.

In the previous edition of the Trigger Point Manual, Simons et al defined an active TrP as “a myofascial TrP that causes a clinical pain complaint. It is always tender, prevents full lengthening of the muscle, weakens the muscle, refers a patient-recognized pain on direct compression, mediates a local twitch response (LTR) of muscle fibers when adequately stimulated, and, when compressed within the patient’s pain tolerance, produces referred motor phenomena and often autonomic phenomena, generally in its pain reference zone, and causes tenderness in the pain reference zone.”⁴⁹ Similarly, a latent TrP was defined as “a myofascial TrP that is clinically quiescent with respect to spontaneous pain; it is painful only when palpated. A latent TrP may have all the other clinical characteristics of an active TrP and always has a taut band that increases muscle tension and restricts range of motion”.⁴⁹ Members of the International Association for the Study of Pain and the American Academy of Pain Medicine considered the presence of tender spots causing local pain and a re-creation of a patient’s symptoms as essential diagnostic components of myofascial pain syndrome (MPS).⁵⁰ Tough et al found that the most commonly applied criteria in research included a tender spot within a taut band of a skeletal muscle, the patient’s pain recognition, a predictable pain referral pattern, and an LTR.⁵¹

Latent TrPs, characterized by motor dysfunction, including stiffness and restricted range of motion, and the presence of referred pain, are far more common than active TrPs, which also feature spontaneous local pain. It has now been established that latent TrPs contribute to the process of nociception, but without reaching the threshold to activate ascending pathways from the dorsal horn (DH) to the brain.^{53–55} Mense suggested that referred pain from latent TrPs may occur when normally ineffective synapses to DH neurons are being sensitized.⁵⁶ A panel of 60 experts from 12 countries agreed through a Delphi study process that the reproduction of symptoms experienced by patients and the recognition of pain are the main clinical differences between active and latent TrPs.⁵² Box 1-1 identifies the clinical characteristics of TrPs identified by Simons, Simons and

Travell,⁴⁹ and by expert opinion from the Delphi study. In addition, active TrPs feature larger referred pain areas and higher pain intensities than latent TrPs,⁵⁷ and their overlying cutaneous and subcutaneous tissues are usually more sensitive to pressure and electrical stimulation.^{58, 59} The degree of irritability of TrPs is correlated with the prevalence of endplate noise, which is more pronounced at active TrPs.⁶⁰

Box 1-1 Clinical characteristics of trigger points

	Common Findings of TrPs	
Simons, Simons and Travell ⁴⁹	<ul style="list-style-type: none"> ■ Palpable taut band with cross-fiber flat or pincer palpation ■ Hypersensitive spot within the taut band ■ Local twitch response when adequately stimulated ■ May produce motor and autonomic phenomena ■ May prevent full lengthening of the muscle (restricts range of motion) ■ May cause inhibition weakness of the muscle 	
	Active TrPs <ul style="list-style-type: none"> ■ Refers or produces a patient's recognized pain ■ Spontaneous local or referred pain 	Latent TrPs <ul style="list-style-type: none"> ■ Local or referred unrecognized pain ■ Painful only when palpated or needled
Expert opinion Delphi study ⁵²	<ul style="list-style-type: none"> ■ Reproduce any symptom(s), not just pain, experienced by the patient ■ Patient recognizes the symptom as familiar ■ The symptom(s) may be absent at the moment of the examination, but will appear during manual palpation 	<ul style="list-style-type: none"> ■ Do not reproduce symptoms experienced by the patient ■ Patient does not recognize symptoms caused by cross-fiber flat or pincer palpation

Since 1999, when the last volume of the TrP Manual was published,⁴⁹ much has changed in the scientific understanding of TrPs. Where in the past myofascial pain was commonly attributed to tissue injury, especially damage to the sarcoplasmic reticulum, tissue damage is no longer the prevailing model. The energy crisis hypothesis and subsequent integrated TrP hypothesis were the first attempts to consider MPS in a broader context.⁶¹ Although the integrated TrP hypothesis is still the prevailing model, it is indeed time for a revision of the myofascial pain construct considering current knowledge and evidence of pain science combined with new clinical insights.^{26, 61} It is encouraging that the

quality of myofascial pain research has improved consistently over the past decades.⁶² Although several new hypothetical models have been developed in an effort to better describe myofascial pain,^{63–72} most are still lacking adequate experimental support. To better understand myofascial pain, it is necessary to become familiar with the basics of contemporary pain science and pain mechanisms. This chapter provides a comprehensive review of various pain models and pertinent aspects of nociception, and peripheral and central sensitization.

2. PAIN MODELS

The International Association for the Study of Pain defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage”.⁷³ In 2018, Cohen et al offered an alternate definition of pain: “Pain is a mutually recognizable somatic experience that reflects a person’s apprehension of threat to their bodily or existential integrity.”⁷⁴ In a commentary, Treede critiqued the interpretation by Cohen et al for not considering the multidimensional nature of the pain experience, for broadening the scope from threat to bodily integrity, which is a poorly defined term, and for suggesting that pain recognition requires an outside observer.⁷⁵ The discussion about the optimal definition of pain will likely continue. What is clear is that pain does not necessarily reflect injury, as previously suggested by proponents of a now outdated strict structural-pathology model, and pain, including myofascial pain, can occur without a specific tissue lesion.

A recent study showed that 96% of asymptomatic 80-year-old individuals and 37% of 20-year olds had demonstrable disk degeneration.⁷⁶ Nakashima et al found that in 1211 asymptomatic individuals in their twenties, 73.3% of males and 78.0% of females had bulging disks.⁷⁷ Battie et al showed that spinal degeneration is not the result of aging and excessive wear and tear.⁷⁸ In another study of 393 subjects with a symptomatic a-traumatic full-thickness rotator cuff tear, the symptoms of pain did not correlate with the severity of the injury.⁷⁹ Degenerative changes of the rotator cuff muscles are not a primary source of pain.⁸⁰ These and other studies clearly illustrate that spine and shoulder degeneration are not necessarily correlated to low back and shoulder pain, and in a broader sense, they confirm that a strict biomedical approach is inadequate to understand pain conditions.^{81, 82} On the other hand, another study showed that disk bulges, degeneration, extrusions, protrusions, Modic 1 changes, and spondylolysis were more prevalent in adults 50 years of age or younger with back pain compared with asymptomatic individuals.⁸³ Interpreting imaging studies without clinical correlations can be rather misleading and may result in unnecessary interventions and extensive medical treatments such as surgery, polypharmacy, including an excessive use of opioids, immobilization and bedrest, and increased disability and pain.^{2, 84, 85} In spite of much progress, pain continues to be a poorly understood phenomenon, although multiple pain models have emerged since the publication of the gate control theory.⁸⁶

Historically, many researchers and clinicians, including Travell and Simons, thought

that muscle pain would cause spasms of the same muscle, which, in turn, would cause more pain leading to more spasms.⁸⁷ This vicious cycle hypothesis, known as the pain–spasm–pain cycle, was based on the assumption that pain would excite alpha-motor neurons and possibly even gamma motor neurons. More recent experimental and human evidence has demonstrated that alpha and gamma motor neurons generally are inhibited by nociceptive input from the same muscle.^{88–92} A change in muscle spindle sensitivity may alter proprioceptive functioning, but there is no convincing evidence of facilitation of spindle activity,⁹³ which means that muscle pain does not appear to cause an increase in fusimotor drive.⁹⁴ Nevertheless, proponents of this concept have suggested that TrPs are the result of dysfunctional muscle spindle activation.⁷¹ Although the pain–spasm–pain cycle is frequently referenced, it is a refuted concept based on an outdated and simplified understanding of the structure and function of alpha and gamma motor neurons.^{95, 96}

The updated pain-adaptation model provided new insights.⁹⁷ According to this model, muscle pain inhibits alpha-motor neurons, leading to the activation of antagonists and an overall reduction in motor function. These patterns are, however, not universally applicable either, as Martin et al demonstrated that muscle nociception resulted in excitation of both elbow flexor and extensor muscles.⁹⁸ Activity of motor neurons is not necessarily uniformly reduced.⁹⁶

Hodges and Tucker proposed a new motor adaptation model, realizing that the vicious pain cycle and pain-adaptation hypotheses are inadequate models of motor adaptation.⁹⁹ Instead, they proposed that a redistribution of activity within and between muscles must occur. Pain will likely change the mechanical behavior of muscles by creating modified movements and stiffness, leading to improved protection from further pain or injury, or from threatened pain or injury. Inhibition or facilitation of select agonist and antagonists may occur. They maintained that simple changes in excitability do not explain motor adaptation, but complementary, additive, or competitive changes at multiple levels of the motor system are more likely to be involved.

Combining Hodges and Tucker's motor adaptation model with the TrP model, TrPs change muscle activity. Lucas et al found altered movement activation patterns in shoulder abduction in subjects with latent TrPs in their shoulder musculature.^{100, 101} Bohlooli et al confirmed the findings by Lucas et al, and expanded the concept to faster movements in all movement planes of the shoulder.¹⁰² In a recent study, Schneider et al showed that active TrPs also alter muscle activation patterns.¹⁰³ The characteristic taut bands found in myofascial pain can be considered to be functional adaptations of motor activity within muscles.¹⁰⁴ Muscles with TrPs result in restrictions in range of motion.^{105–110} Trigger points inhibit overall muscle function, leading to muscle weakness without atrophy, or perhaps more accurately, to motor inhibition.¹¹¹

As new data and facts become available, pain theories will evolve. Following the publication of the gate theory in 1965,⁸⁶ which in itself was conceived out of preceding pain models,¹¹² several new models have been formulated. Although the gate control theory provided a strong impulse to take pain seriously and foster research into pain

mechanisms, the model is not perfect and has been modified multiple times since its publication.^{113,114} In 1998, Gifford introduced the mature organism model, which considered the interactions between the periphery and the central nervous system.^{115,116} He maintained that the combination of tissue health, environmental factors, past experiences, and personal beliefs are processed by the central nervous system, leading to specific output mechanisms that involve the motor, neuroendocrine, autonomic, immune, and descending control systems.^{115,116} Melzack also recognized the multidimensional nature of pain when he formulated the neuromatrix model, which, like the mature organism model, aimed to develop a better understanding of the role of the brain.^{112,114,117,118} Melzack specifically included TrPs as sources of peripheral nociceptive input, among many other possible inputs. The neuromatrix and mature organism model are examples of biopsychosocial models of care, which are very much in line with how Travell practiced as a physician. According to Travell, “in this age of specialization, few clinicians are broad enough to see the whole patient and his/her problem . . . understanding with the delicate interplay between the patient’s mind, body, environment is a paramount importance in helping a patient overcome an illness.”¹¹⁹

Although the brain is actively involved in the processing of sensory input and the experience of pain, pain is much more than just a linear process initiated by tissue injury and inflammation. Pain involves the integration of sensory, emotional, and cognitive dimensions. According to Melzack, pain experiences reflect the cultural background of the individual, the context of the circumstances triggering a pain experience and other environmental impacts, psychological variables, stress responses, past experiences, and personal aspects, including genetics.^{112,120} In persistent pain, however, the correlation between pain and tissue injury becomes less pronounced and may even be nonexistent.¹²¹ It has been established that nociception is not necessary for the perception of pain.^{122,123} In persistent pain conditions, the experience and degree of pain do not provide meaningful information about the state of the tissues, but this should not be interpreted to mean that peripheral nociceptive input from specific tissues or regions would never be irrelevant.^{26,124}

Nijs et al have proposed guidelines to differentiate low back pain disorders with predominant nociceptive pain, neuropathic pain, and central sensitization.¹²⁵ They defined nociceptive pain as pain arising from actual or threatening damage to nonneural tissue due to the activation of nociceptors, or as pain attributable to the activation of the peripheral receptive terminals of primary afferent neurons in response to noxious chemical, mechanical, or thermal stimuli, which may include myofascial pain. Neuropathic pain was defined as “pain caused by a primary lesion or disease of the somatosensory nervous system,” such as a lumbar radiculopathy. Central sensitization was defined as “an amplification of neural signaling within the central nervous system that elicits pain hypersensitivity,” “increased responsiveness of nociceptive neurons in the central nervous system to their normal or subthreshold afferent input,” or “an augmentation of responsiveness of central neurons to input from unimodal and polymodal receptors.”¹²⁵ Nijs et al consider TrPs as peripheral sources of nociception in patients with low back pain

in line with Moseley' findings that "elimination of myofascial TrPs is an important component of the management of chronic musculoskeletal pain."¹²⁶

A common theme in the various pain models is that clinicians would need to identify which pain mechanisms are dominant in a given patient to determine the optimal treatment parameters. In Gifford's mature organism model, exercise and manual therapies are thought to be most effective when the pain is primarily input-dominant or nociceptive, meaning that tissue injury or abnormal peripheral nerve input are the most important causative factors. Even under those circumstances, Gifford recognized that psychological dysfunction, such as anxiety, or a poor understanding of the problem would require a different approach emphasizing the inclusion of cognitive and affective aspects.¹¹⁵ In cases where the output-dominant processes are prevailing, advocates of this model emphasize that the focus of therapy should be on therapeutic pain science education, gentle exercise, and pain-free interventions to avoid further sensitization.^{127–129} Pain science education should not be offered as a stand-alone intervention.¹³⁰ Furthermore, even when pain science education is included in the care, developing a therapeutic alliance with the patient is essential, as is listening to the patient without restricting time constraints.^{131,132} See Chapter 5 for more on the therapeutic alliance.

Following that thought process, some clinicians and researchers have concluded that considering TrPs in the clinical thought process would reflect an antiquated model in the context of modern pain sciences, based on the assumption that "the issues are not in the tissues," and that pain is produced by the brain or by other mechanisms.^{72,133,134} Quite to the contrary, the manual examination of peripheral joints, muscles, skin, and fascia continues to be important, especially within a contemporary pain science and neuromatrix perspective.¹³⁵ There is much evidence that both active and latent TrPs provide a mechanism of peripheral nociceptive input that can contribute to both peripheral and central sensitization.^{25–27,126,136} Referred pain, or secondary hyperalgesia, is a characteristic of central sensitization.¹³⁷ Experts reached agreement that referred pain from TrPs can include different sensory sensations, including pain, a dull ache, tingling, or burning pain.⁵² In the aforementioned Delphi study, the experts proposed the term "referred sensation" instead of referred pain because of the variety of symptoms associated to TrP stimulation.⁵²

3. NOCICEPTION

Peripheral and central sensitization are important aspects of myofascial pain and other clinical pain syndromes.^{27,138} There are three distinct parts of the nervous system responsible for the perception of pain, including afferent pathways from the periphery to the DH and from the DH to higher centers in the central nervous system; integration centers in the brainstem, midbrain, and cortex, among others; and efferent pathways from the brain to the spinal cord.¹³⁹ Sensitization is characterized by a reduction in pain thresholds and an increase in responsiveness of peripheral nociceptors and plays a critical role in pain syndromes,³ including MPS.^{6,26,27,140} There is emerging evidence that as

persistent sources of nociceptive input, TrPs contribute to the propagation and maintenance of pain and central sensitization.^{26,27,141,142} Ongoing, strong, and sustained peripheral nociceptive input leads to profound neuroplastic and even anatomic changes, including changes in gray matter.^{123,143–146} Anatomic volume changes may include the brainstem, the right anterior thalamus, the dorsolateral prefrontal cortex, the somatosensory cortex, and the posterior parietal cortex.¹⁴⁷ Treatments aimed at reducing pain may reverse the anatomic changes.^{148,149} Of interest is that mechanical stimuli do not contribute as much to peripheral stimulation as thermal and chemical stimuli do.^{114,150} Central nociceptive neurons respond to the synaptic input from peripheral nociceptors.¹⁴³ Because the latter have a primary warning function, they can generate signals before tissue injury occurs. Central sensitization is commonly maintained by ongoing peripheral nociceptive input, which has been described for fibromyalgia,¹⁵¹ musculoskeletal pain,¹⁵² neuropathic pain,¹⁵³ and myofascial pain,¹³⁷ among others. Reichling et al wrote an exceptionally lucid and thorough review that is the basis for many of the concepts referred to in this section along with several other informative reviews.^{3,154,155}

There are four stages of nociception, namely transduction, transmission, perception, and modulation (Box 1-2).

Box 1-2 Stages of nociception

Transduction
Transmission
Perception
Modulation

Nociception is the process of perception of painful sensations, which starts with the detection of potentially painful stimuli by the peripheral terminals or nerve endings of afferent nerve axons, called primary afferent fibers with cell bodies located in the dorsal root ganglion (DRG) for the body and in the trigeminal ganglion for the face. The main afferent nerve fiber types are the small-diameter, myelinated, faster-conducting A δ (group IV) fibers that mediate localized pain sensations and the small-diameter unmyelinated, slower conducting C (group IV) fibers that mediate more dull, poorly localized, and delayed pain. It is important to understand that not all small-diameter, slowly conducting fibers are nociceptive. Skeletal muscle and cutaneous nerves feature low-threshold group IV mechanoreceptors. Cutaneous nerves also include thermoreceptors (Figure 1-1).^{156,157}

Figure 1-1. Overview of somatosensory input and two ascending pathways of somatic sensation. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

$A\delta$ nociceptors are divided into two main classes. Type I or high threshold mechanical nociceptors are polymodal receptors that respond to both mechanical and chemical stimuli. Normally, type I receptors have a high thermal threshold, but with prolonged heat stimulation, their threshold is reduced and they can become sensitized. Type II $A\delta$ nociceptors have a high mechanical threshold, but a low thermal threshold.^{158, 159} C fibers have either mechanothermal nociceptors, cold nociceptors, or polymodal nociceptors (Figure 1-2).¹⁶⁰

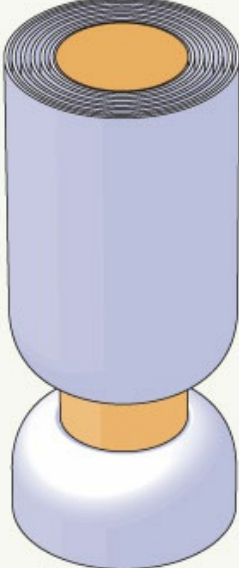

Axons from skin	A α	A β	A δ	C
Axons from muscles	Group I	II	III	IV
				
Diameter (μm)	13–20	6–12	1–5	0.2–1.5
Speed (m/sec)	80–120	35–75	5–30	0.5–2
Sensory receptors	Proprioceptors of skeletal muscle	Mechanoreceptors of skin	Pain, temperature	Temperature, pain, itch

Figure 1-2. Various sizes of primary afferent axons. The axons are drawn to scale, but they are shown 2000 times larger than life size. The diameter of an axon is correlated with its conduction velocity and with the type of sensory receptor to which it is connected. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Noxious stimuli can be located outside the body, such as exogenous mechanical stimuli, or can arise internally from injured and inflamed tissues, referred to as endogenous stimuli. Both exogenous and endogenous noxious stimuli produce a variety of algescic and proalgescic mediators, including lipid mediators, cytokines, protons, and neurotransmitters. Both activate ionotropic (ligand-gated ion) channels and metabotropic (G-protein-coupled) receptors in the cell membrane.¹⁶¹ Ionotropic receptors are transmembrane molecules that can “open” or “close” a channel to transport smaller particles, such as K⁺, Na⁺, Cl⁻, and Ca²⁺ ions, across the cell membrane. Ionotropic receptors are closed until a specific ligand binds to the receptor, such as substance P, protons, adenosine triphosphate (ATP), or

glutamate. Metabotropic receptors do not feature an ion channel. They are linked to a “G-protein” and have a guanine nucleotide-binding. After activating a G-protein, the protein activates another molecule, referred to as the “secondary messenger.” The activation of secondary messengers, particularly the protein kinases, involves phosphorylation of ion channels, which increases the opening time or opening probability of an ionotropic channel. As an example, bradykinin (BK) and prostaglandins (PG) act on metabotropic receptors.^{162–164} Metabotropic channels are always slower than ionotropic channels. Capsaicin, ATP, nerve growth factor (NGF), and protons are common stimulants for muscle nociceptors by activating such receptors.^{156, 165}

Many substances have multiple receptors. For example, there are six families of human glutamate receptors, including three types of ionotropic receptors, namely AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid), NMDA (*N*-methyl-d-aspartate), and kainate receptors, and three types of metabotropic receptors (Groups I-III),¹⁶⁶ which shows that glutamate plays a key role in many processes.¹⁵⁴ In experimental studies, different substances, such as glutamate or capsaicin, are commonly used to elicit local and referred muscle pain (Figure 1-3).^{167–170}

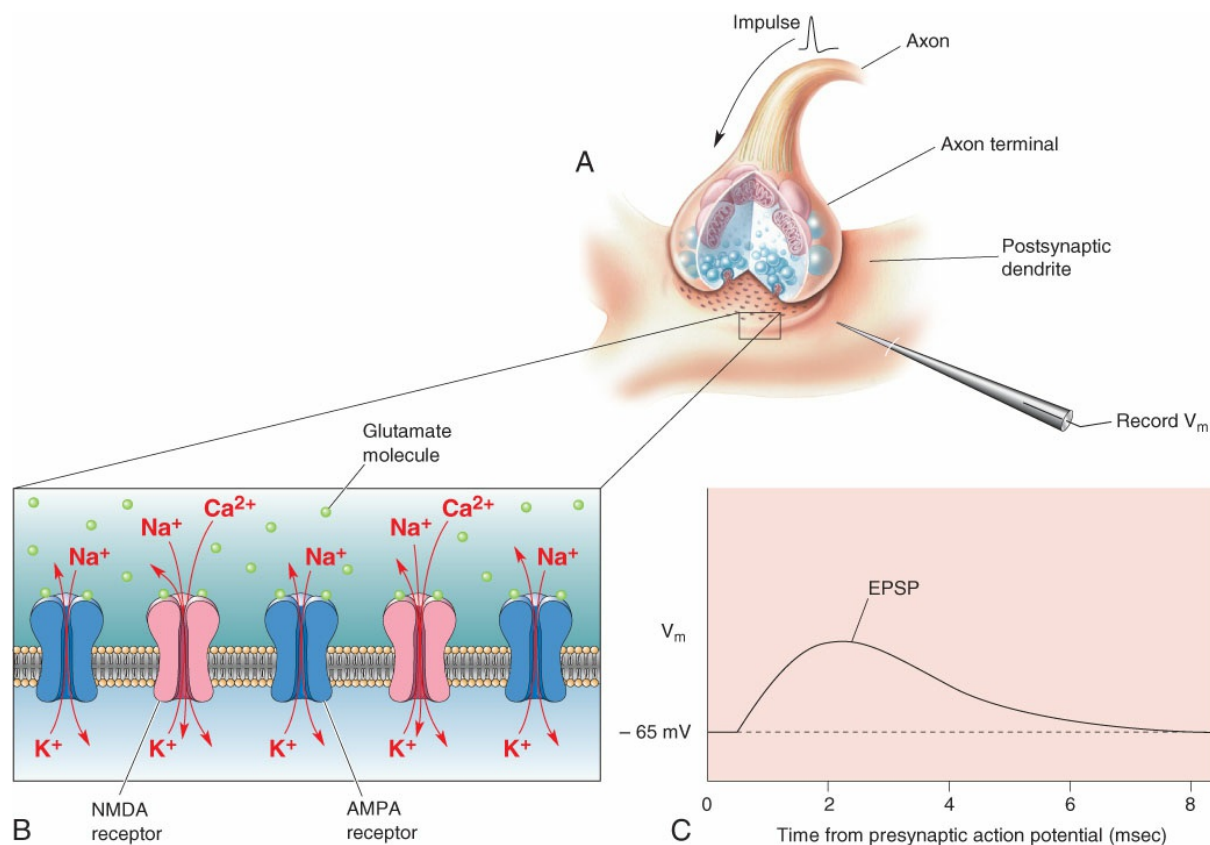

Figure 1-3. The coexistence of NMDA (*N*-methyl-d-aspartate) and AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors in the postsynaptic membrane of a central nervous system synapse. (A) An action potential arriving in the presynaptic terminal causes the release of glutamate. (B) Glutamate binds to AMPA receptor channels and NMDA receptor channels in the postsynaptic membrane. (C) The entry of Na through the

AMPA channels, and Na and Ca² through the NMDA channels, causes an EPSP. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

The first neurotrophic factor implicated in producing pain was NGF. Injections of NGF into low back musculature induced prolonged hypersensitivity in rats.¹⁷¹ Other studies demonstrated that peripheral administration of NGF caused thermal and mechanical hyperalgesia.^{172, 173} Injections of NGF in the tibialis anterior muscle and its overlaying fascia triggered significantly greater hyperalgesia in the fascia.¹⁷⁴ The thoracolumbar fascia was more sensitive than the tibial fascia.¹⁷⁴ Increased levels of NGF have been shown in the cerebrospinal fluid of patients with multiple sclerosis and central neuropathic pain,¹⁷⁵ diabetic neuropathy,¹⁷⁶ chronic arthritis,¹⁷⁷ and rheumatoid arthritis.¹⁷⁸ NGF acts at the high-affinity NGF tropomyosin receptor kinase A (TrkA) receptor and at the low-affinity p75 receptor. The NGF-activated TrkA receptor selectively triggers several intracellular signaling pathways via the binding of specific effector proteins to phosphorylated docking sites. The activation of the p75 receptor also activates several intracellular pathways. The two receptors function together: p75 improves the binding at the TrkA receptor. A loss of function of the TrkA receptor causes insensitivity to pain, which illustrates its important role in pain perception.¹⁷⁹ NGF is part of a family of growth factors referred to as neurotrophins, which also includes brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3), among others.¹⁸⁰ BDNF acts at the TrkB receptor and NT-3 at the TrKC receptor.¹⁸¹

Neuropeptides like substance P and calcitonin gene-related peptide (CGRP) act at peptidergic nociceptors. Substance P is released from peripheral nerve endings of DRG neurons, causing neurogenic inflammation, and in the DH where it binds to neurokinin type 1 receptors.¹⁸² CGRP is well known for its role as a vasodilator, especially in the cardiovascular system and with migraine headaches,¹⁸³ but it also plays a major role in muscle physiology, especially in skeletal muscles excitation-contraction coupling.¹⁸⁴ In addition, CGRP enhances the expression of dihydropyridine receptors,¹⁸⁵ which is relevant for TrPs and myofascial pain (see Chapter 2). Motor endplates and sensory nerves feature CGRP immunoreactivity.¹⁸⁶ CGRP is released from motor neurons following electrical stimulation¹⁸⁷ and binds to membrane receptors of the skeletal muscle.^{188, 189} NGF regulates the expression of substance P and CGRP within the spinal cord.¹⁹⁰ When NGF antibodies are administered, the upregulation of CGRP and mechanical hyperalgesia are suppressed.¹⁹¹

3.1. Nociception and Transduction

Transduction is the molecular process by which thermal, chemical, and mechanical stimuli are converted to electrical impulses or electrical energy in the form of an action potential. Transduction takes place at the cell membrane of the peripheral nerve ending. The electrical impulses or action potentials are transmitted centrally along primary afferent

nerve fibers to DRG neurons. Action potentials from the first-order DRG neurons travel centrally through short afferent fibers to spinal DH neurons. Different fiber types synapse to second-order neurons in the DH in specific laminae: A δ and C fibers terminate in Rexed laminae I and II. The substantia gelatinosa (lamina II) is an important region with many synaptic connections between primary sensory afferent neurons, interneurons, and ascending and descending fibers allowing modulation of the pain signal transmission,¹⁵⁴ which is a key aspect of the gate control theory.¹¹⁴ A δ fibers also terminate in lamina V. The distribution of A δ and C fiber terminations in the DH is determined to a large degree by the type of receptor that is activated, and therefore, the process is receptor and stimulus specific (Figure 1-4).¹⁵⁹

Figure 1-4. Spinal connections of nociceptive axons. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Signal transduction is usually considered as a process of information transfer mediated by neurotransmitters, hormones, or cytokines that bind to transmembrane receptors at the cell surface, such as substance P, somatostatin, glutamate, dynorphin, and cholecystokinin (CCK), among others.¹⁹² Transduction is enhanced by intracellular processes mediated by second-messenger pathways such as G-protein membrane receptors; however, there are many other possible signal transduction pathways. Berridge identified as many as 19 different signal transduction cascades.¹⁹³ Transduction can be modulated downward (inhibited) by receptor antagonists, such as the acid-sensing ion channels (ASICs) receptor antagonists oxytocin and arginine vasopressin,¹⁹⁴ and by the transient receptor potential cation channel subfamily V member 1 (TRPV1) channel antagonist ARA 290.¹⁹⁵ Some transducers reside on nonneuronal cells, which, when stimulated, release mediators that signal to the nociceptor, such as the keratinocyte and the satellite glial cell.

3.2. Nociception and Transmission

Nociceptive impulses from the DH are transmitted primarily via the ascending neospinothalamic tract to the thalamus, the contralateral parietal somatosensory cortex, and other cortical centers, to provide the accurate location of pain. The neospinothalamic tract is a fast-conducting discriminative tract (Figure 1-5). On the other hand, the paleospinothalamic tract is a slower conducting tract, corresponding to the spinomesencephalic, the spinoreticulothalamic, and spinoparabrachial projections (Figure 1-1). The cortical representation of pain involves the anterior cingulate cortex and the posterior operculo-insular cortex for C-afferent stimulation. The contralateral somatosensory cerebral cortex in the parietal lobe for nociceptive A δ afferent stimulation and in associated areas such as the amygdala, the thalamus, the insula, and the prefrontal and posterior parietal cortices.^{139, 196, 197} During a pain experience, these areas appear to communicate with each other.¹²⁸ Modulation that amplifies or inhibits the response to nociceptive stimulation occurs at all levels of transduction and transmission. Box 1-3 summarizes the stages of peripheral nociception.

Figure 1-5. The spinothalamic pathway. This is the major route by which pain and temperature information ascend to the cerebral cortex. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Box 1-3 The stages of peripheral nociception

Stimuli	Extracorporeal Thermal Mechanical Chemical Endogenous (Extracellular Milieu) Injury
---------	--

	Inflammation
Cell-surface detection	Receptors Voltage-gated ion channels G-Protein-coupled receptors
Transduction	Conversion of stimuli to action potentials
Modulation	Satellite glial cells Facilitation or inhibition Cell membrane Intracellular Dorsal horn Estrogen Descending inhibitory system
Transmission	Afferent nerve fiber to Dorsal root ganglion neuron Dorsal root ganglion neuron to dorsal Horn neuron
Sensitization	Neuroplastic changes (transcription)
Chronic pain	Transcription Sensitization

3.3. Nociception and Sex Differences

As a side note, many studies suggest that women are more sensitive to noxious stimuli and have greater pain sensitivity.^{198,199} The mechanisms underlying these sex differences are poorly understood,²⁰⁰ but it is likely that psychological, cultural, and biological factors all contribute to these differences. Biological factors may include hormonal, genetic, behavioral, and environmental aspects.^{201–206} Total sleep deprivation triggered significant alterations in the descending pain inhibition in women but not in men.²⁰⁷ In general, women had greater pain responses with electrical and thermal stimuli than men,²⁰⁸ but when comparing older men and women, there were no differences in pain sensitivity or brain activation.²⁰⁹ Most women display a lower threshold to painful stimuli and more brain activity in regions associated with affective pain.²¹⁰ However, when anxiety was better controlled, the differences between men and women were less pronounced.²¹¹ Intolerance of uncertainty was relevant in both sexes and increased the pain intensity.²¹² Women with shoulder pain exhibited a lower mechanical and thermal pain threshold than men.^{213,214} Brain studies have confirmed that women have a greater activation of the anterior cingulate cortex.²¹⁵

Differential sex responses to nociceptive stimuli suggest that there is hormonal modulation of transduction or transmission to the cerebral cortex. Hormones are likely to

influence the efficacy of endogenous pain-control systems and the integration of nociceptive input.^{216,217} For example, estradiol potentiates ASICs function and also BK signaling, accounting for at least some of the observed sex difference in responsiveness to nociceptive stimuli, with females being more sensitive.^{218,219} One method of potentiation is the increase in the density of cell-surface receptors by the method of transcription, or the synthesis of more receptor molecules, which are moved to the cell surface by a process of exocytosis. The action of estrogen is rapid, however, occurring over a matter of seconds, indicating a different mechanism of action than gene transcription.²²⁰ Second-messenger signaling pathways for the induction of mechanical hyperalgesia are estrogen-dependent. This topic is discussed in greater detail in Chapter 4 on perpetuating factors.

3.4. The Extracellular Milieu

The extracellular milieu contains inflammatory mediators and chemokines produced by immune system cells. Immune cells act on cell-surface receptors through these mediators. Individual neurotrophic factors released by immune system cells act on different subpopulations of nociceptors, contributing to specific pain syndromes. These mediators are the current or potential targets of therapeutic agents, such as nonsteroidal anti-inflammatory drugs, for PG (Figure 1-6). The extracellular matrix is a ligand for cell-surface receptors called integrins that uniquely signal both from inside the cell to the extracellular matrix and from the extracellular matrix into the cell. Inhibiting specific integrins, eg, blocking antibodies, selectively attenuates mechanical hyperalgesia induced by specific proinflammatory cytokines. The extracellular matrix can also concentrate chemokines and neuropeptides to present them to their cell-surface receptors.

Figure 1-6. Peripheral chemical mediators of pain and hyperalgesia. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Supporting cells actively participate in the nociceptive process. Glial cell-line-derived neurotrophic factors are upregulated in the presence of pain. Glial cells in the central nervous system that express transient receptor potential (TRP) ion channels are important mediators of pain sensation; however, glial cells are also found in the periphery, where they tightly enwrap DRG neurons. Glial cells in the peripheral nervous system are referred to as satellite glial cells.²²¹ They have the potential for regulating neuronal excitability through the release of mediators such as interleukin-1 β and other cytokines, and ATP that bind to purinergic receptors on the cell membrane.^{221–224} Of interest is that a release of ATP and the activation of purinergic P2 receptors, specifically P2X₇, recruits phagocytes, including neutrophils, macrophages, and dendritic cells (DCs) to the site of injury. The activation of P2X₇ receptors increased the motility of DCs, which was further amplified by pannexin 1 channels. In addition, pannexin 1 increased the permeability of the plasma membrane, leading to an additional ATP release.²²⁵

As mentioned previously, the detection of nociceptive stimuli begins at the cell-surface membrane of the peripheral nerve ending, where a variety of receptors are located. These receptor families, which respond to one or more potentially noxious mechanical, thermal,

and chemical stimuli, are critical to the process not only of nociception, but also to the process of sensitization wherein nociceptive impulses are amplified and prolonged, resulting in hyperalgesia and allodynia, and chronic pain states. Key to the excitation of the peripheral nerve ending is the binding of ligands or other mediators like protons to specific cell-surface or ionotropic receptors. Different receptor types contribute to different types of pain, and excite discrete groups of neurons in laminae I, II, and V in the DH (Figure 1-4).

Peripheral primary afferent nociceptors have a particular ability to be sensitized. Repeated input of nociceptive stimuli lowers the threshold to excitation and thus enhances and prolongs the response to stimulation, a function relevant to both inflammatory and neuropathic pain syndromes. However, nociceptors that transduce pressure (and touch and special senses such as vision, taste, and smell) desensitize with repeated stimulation. Nociceptor sensitization involves second-messenger signaling pathways like cyclic adenosine monophosphate (cAMP)/protein kinase A and protein kinase C. Sodium, potassium, and calcium ion channel families are all involved in sensitization. The mechanisms include phosphorylation of the channels, a process that is faster than transcription, which requires new protein synthesis, and transcription that inserts a newly synthesized ion or other channel receptor molecule into the plasma membrane. A calcium-dependent exocytotic insertion of TRPV1 receptors to the neuronal plasma membrane is one such mechanism that increases the neuronal excitability.²²⁶ Additionally, there are nociceptors that become responsive only to mechanical stimulation when exposed to inflammatory mediators.^{227, 228} Modulation of nociceptive input occurs not only at the peripheral terminal of the afferent neuron, but also at the neuronal level in the DRG.²²⁹

There are categorized nociceptors in various tissues that are based on their responses to different ligands. The skin, for example, has two main subtypes of nociceptors. One subtype consists of peptidergic afferents that operate via neuropeptides like substance P and CGRP, and respond to painful heat stimuli. The other subtype consists of nonpeptidergic afferents that are primarily mechanoreceptors. Both use l-glutamate as their primary excitatory neurotransmitter in their DH synaptic connections to second-order neurons and interneurons.

Families of membrane receptors respond to one or more types of stimuli. When activated, a receptor will be open to the passage of certain ions, like sodium or potassium, resulting in the generation of an action potential. One such family of membrane receptors is the ligand-gated TRP nonselective ion channel family that detects all three types of potential nociceptive stimuli and are therefore called polymodal receptors.^{230, 231} They play a crucial role in pathologic pain perception and were first described as the receptors of capsaicin.²³² They are only one of many types of ion channels (Figure 1-7) that convert sensory stimuli into nociceptive signals. There are 6 TRP subfamilies and 28 nonselective cation channels (TRPV1–6, TRPM1–8, TRPC1–7, TRPA1, TRPP1–3, and TRPML1–3).²³³ TRP ion channels are also involved in the transduction of chemical stimuli. TRPV1 is expressed in trigeminal and dorsal root sensory ganglia, and also outside the nervous system, for example, in the gastrointestinal tract and the kidneys.²³⁴ Of interest is that oxytocin can reduce pain via TRPV1 receptors, which implies that TRPV1 is also an

ionotropic oxytocin receptor.²³⁵

Figure 1-7. A membrane ion channel. Ion channels consist of membrane-spanning proteins that assemble to form a pore. In this example, the channel protein has five polypeptide subunits. Each subunit has a hydrophobic surface region (shaded) that readily associates with the phospholipid bilayer. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Other such membrane receptors include the ASIC family that detects protons in the extracellular milieu,^{236,237} and Piezo cation channels that detect mechanical stimuli.²³⁸ There are six known ASIC receptors, namely, ASIC1a and ASIC1b, ASIC2a and ASIC2b, ASIC3, and ASIC4.²³⁹ TRPV1 ion channels and ASIC3 are likely to participate in the development and maintenance of prolonged secondary allodynia and hyperalgesia.²⁴⁰ Neuroimmune interactions, critical for the development of chronic pain, also play a role in the development of both peripheral and central sensitization. ASIC receptors are activated where the pH in the extracellular milieu drops below normal, even in the absence of tissue

damage.

Piezo channels sense light touch, proprioception, and vascular blood flow, and they open in response to mechanical stimuli, although many aspects of their channel function remain unknown.^{238,241} There are two types of Piezo channels. Piezo 1 channels are activated by fluid pressure and primarily expressed in nonsensory tissues such as the kidneys and red blood cells. They are involved in red blood cell homeostasis.²⁴¹ Piezo 2 channels are located in sensory tissues, such as DRG sensory neurons and Merkel cells, and are involved with light touch and proprioception (Figure 1-8).^{238,241} The Piezo channels are sensitized by G protein-coupled pathways, linked to the BK receptor and the cAMP receptor likely through the activation of protein kinase A and protein kinase C. They are excitatory channels that allow Ca^{2+} to enter the cell, which may lead to activating intracellular Ca^{2+} signaling pathways.²⁴¹ There are other ligand-gated ion and G-protein-coupled receptors that are also involved in nociceptive sensory perception. They respond to a variety of chemical stimuli, including purines and PG.²⁴² The activation of these cell-surface receptors converts nociceptive stimuli to nerve impulses.

Figure 1-8. Somatic sensory receptors in the skin. Hairy skin and glabrous skin have a variety of sensory receptors within the dermal and epidermal layers. Each receptor has an axon and, except for free nerve endings, all of them have associated nonneural tissues. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

The activation of specific ion channels is not a simple, one-step process. The state or availability of such cell-surface receptors as TRP ion channels or ASICs is enhanced or inhibited by interaction with other ion channels that can be activated by extracellular stimuli or intracellular calcium.^{243–245} Different receptors respond to different stimuli or at different thresholds:

- Piezo receptors are relevant to the functioning of mechanoreceptors.^{246,247}
- TRPV1 responds to heat, low pH, to capsaicin, and probably also to mechanical stimuli. NGF promotes chronic pain in humans and its effect is mediated through TRPV1 receptors.²⁴⁸
- Serotonin receptors exist on peripheral nerve terminals as well as the central nervous system, where they activate inhibitory interneurons. The activation of peripheral 5-HT1B, 5-HT2A, and 5-HT3 receptors inhibits mechanical hyperalgesia.²⁴⁹
- The P2Y receptor agonist uridine-5'' triphosphate enhances the activity of the ASICs, which sense extracellular protons.²⁵⁰

3.5. Nociception and Modulation

Modulation at the Cellular Level

Modulation either amplifies or inhibits the response to nociceptive stimulation, which occurs at all levels of transduction and transmission. With respect to intracellular modulation, cAMP was the first intracellular signaling molecule implicated in nociceptor sensitization. The pathway is activated by a G-protein-couples receptor. When coupled to a stimulatory G-protein, it activates adenylyl cyclase, leading to the production of cAMP and the downstream activation of protein kinase A (PKA). PKA, in turn, phosphorylates voltage-gated ion channels and thereby regulates neuronal excitability (Figure 1-9). There are a number of such second-messenger families. One particular second-messenger family is mediated by the epsilon isoform of protein kinase C (PKC) that is found on almost all DRG neurons, but only a subpopulation of DRG neurons is activated by it in pain. Reichling et al described a potential mechanism of neuronal plasticity in peripheral neurons in response to the exposure of primary afferent nerve fibers that have been exposed to an acute inflammatory insult followed by a low concentration of an inflammatory mediator.³ They called this “hyperalgesic priming.” It is also dependent on the activation of the epsilon isoform of PKC and a switch in intracellular signaling pathways from PKA alone to PKA and PKC together. The activation of other intracellular protein kinases may also play a role, for example in the neuroplastic changes associated with late-phase long-term potentiation.

Figure 1-9. The stimulation and inhibition of adenylyl cyclase by different G-proteins. (A) Binding of norepinephrine (NE) to the receptor activates G_s , which, in turn, activates adenylyl cyclase. Adenylyl cyclase generates cyclic adenosine monophosphate, which activates the downstream enzyme protein kinase A. (B) Binding of NE to the α_2 receptor activates G_i , which inhibits adenylyl cyclase. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Intracellular organelles, such as mitochondria (Figure 1-10), play a role in nociceptor sensitization, especially in the peripheral terminal, which is at a far distance from the cell body. The peripheral terminal has a high concentration of mitochondria that regulate intracellular calcium, aerobic energy metabolism, generation of reactive oxygen species (ROS), and apoptosis. There are five mitochondrial electron transport chain complexes and the inhibition of any of these reduces pain in a number of pain syndromes, including HIV syndrome, cancer, and diabetic neuropathic pain models.²⁵¹

A

B

Figure 1-10. The role of mitochondria. (A) Components of a mitochondrion. (B) Cellular respiration. Adenosine triphosphate is the energy currency that fuels biochemical reactions in neurons. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Higher-level organization at the cellular level plays an important part in nociceptor excitation, by increasing the likelihood of depolarizing the membrane and initiating an action potential. This includes multimolecular complexes in the plasma membrane, intracellular organelles in the cytoplasm, such as the mitochondria, Golgi apparatus, endoplasmic reticulum, and cytoskeleton (Figure 1-11A and B). Micro-domains in the plasma membrane extend the effect of a single ion channel being activated by phosphorylation. A small depolarization produced by a transducer can be amplified, for example, in response to a specific stimulus that leads to single ion channel activation. A micro-domain acts by bringing molecular elements of a signaling pathway together, excludes elements of other pathways, and thereby produces a very efficient signaling complex, also known as a “signalosome.” There are about 200 different types of these signalosome components with extensive interconnectivity pathways, which is why the signalosome complex is more accurately described as “a non-linear network of interacting circuits.”¹⁹²

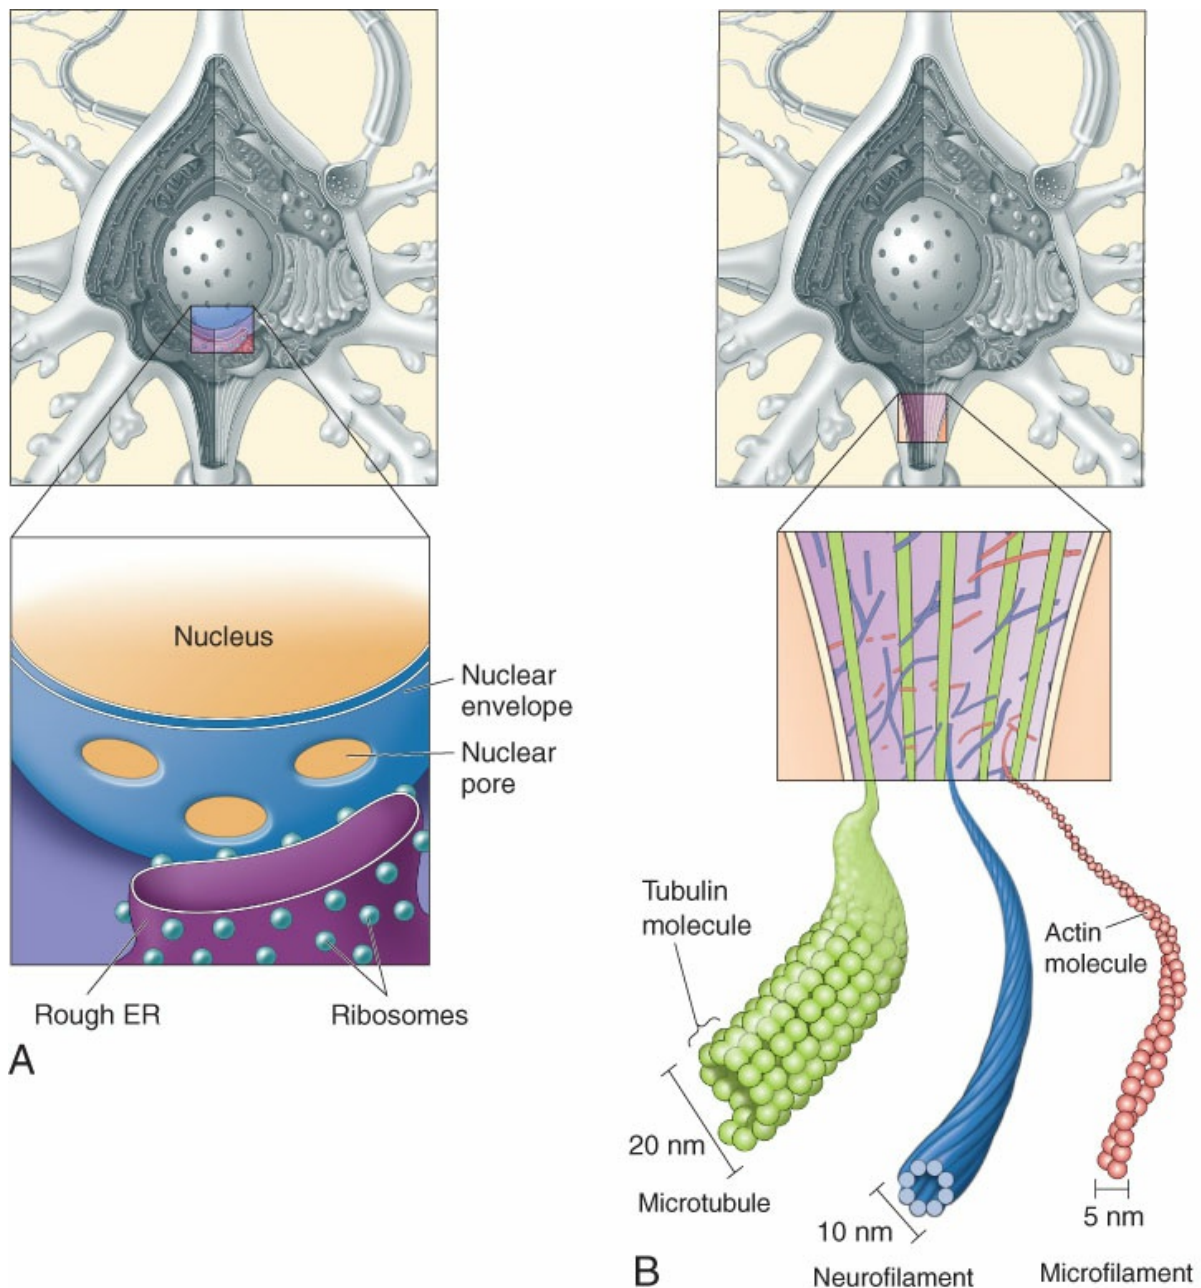

Figure 1-11. A, Rough endoplasmic reticulum. B, Components of the cytoskeleton. The arrangement of microtubules, neurofilaments, and microfilaments gives the neuron its characteristic shape. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Top-Down Modulation

Throughout the central nervous system are many opportunities to modify nociception and pain messages. Modulation can be facilitatory or inhibitory.²⁵² The main control system from higher brain areas to the DH, commonly referred to as the descending inhibitory system, influences not only pain levels but also the pain experience.²⁵³ The anterior cingulate cortex and amygdala can modulate nociception by interacting with the

periaqueductal gray (PAG) to activate descending opioidergic pain inhibition.²⁵⁴ The PAG, rostral ventral medial medulla (RVM), nucleus raphe, and interactions between these systems play a key role in the inhibition of pain from the brain to the spinal cord.^{255–257} The PAG does express mu-opiate receptors, enkephalin and beta-endorphin, which appear to contribute to the PAG's endogenous antinociceptive capability (Figure 1-12).²⁵⁸ CCK, a peptide found in the PAG, can reduce the antinociceptive activity of the PAG.²⁵⁹ Of interest is that substance P in the PAG also has an antinociceptive effect by activating descending inhibition, whereas in the spinal cord, it increases nociception.^{260,261} Descending pathways from the nucleus raphe terminate in laminae I, II, and IV,²⁶² where they may inhibit the presynaptic release of substance P, among others.¹⁵⁴

Figure 1-12. Descending pain-control pathways. A variety of brain structures, many of which are affected by behavioral state, can influence activity within the periaqueductal gray matter (PAG) of the midbrain. The PAG can influence the raphe nuclei of the medulla, which, in turn, can modulate the flow of nociceptive information through the dorsal horns of the spinal cord. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

The control of pain transmission is a bidirectional process.²⁶³ For example, descending

excitatory pathways from the brain can activate serotonin receptors, which may exacerbate spinal mechanisms of pain through the activation of spinal TRPV1 terminals.^{264–268} However, serotonergic projections can also trigger inhibition, dependent upon which subtypes of serotonin receptors are targeted. Several studies have confirmed that the activation of 5-HT_{2A} and 5-HT₃ receptors is facilitatory, and the activation of 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, and 5-HT₇ receptors is inhibitory.^{269–272} Approximately 20% of neurons from the RVM are serotonergic, but the majority is thought to be GABAergic (gamma-aminobutyric acid) and glycinergic.²⁷³ It is not yet known how the RVM modulates the spinal levels of serotonin. When the descending inhibitory system is inhibited, pain may become chronic.^{274–276}

Characteristic of chronic pain conditions, such as central neuropathic pain, MPS, fibromyalgia, and complex regional pain syndrome, is a dysfunction of the descending inhibitory system to modulate pain, which has a profound impact on the degree of chronic pain an individual will experience.^{277, 278} Bannister and Dickenson emphasized that top-down processing pathways do exert significant controls over spinal neuronal processes, mostly through the actions of norepinephrine (NE) and 5-HT.²⁷⁹ NE reuptake inhibitors such as tramadol, tapentadol, or duloxetine can be helpful in reducing pain. Nuseir and Proudfit confirmed that noradrenergic descending projections can also exert a bidirectional control of nociceptive inputs.²⁸⁰

A specific mechanism of top-down inhibition is referred to as diffuse noxious inhibitory controls (DNICs), which require a noxious input that can modulate spinal wide dynamic neurons through the subnucleus reticularis dorsalis, caudal medulla, and nucleus raphe magnus.^{281–286} It is conceivable that the therapeutic pain-reducing effect of TrP dry needling, which is often perceived as a noxious stimulus, may activate the DNIC system. Of interest is that there are genetic differences in DNIC. For example, non-Hispanic white individuals experienced a significantly greater reduction in pain than African Americans.²⁸⁷ Furthermore, a systematic review demonstrated that male subjects may have a more efficient DNIC than females,²⁸⁸ although individual studies do not always confirm this observation.²⁸⁹ In conclusion, altered neurophysiologic processing is a major factor in persistent pain problems. How to assess this altered processing will be reviewed in the next section.

QUANTITATIVE SENSORY TESTING

Carol A. Courtney

Establishing the relevance of altered somatosensory findings during patient examination may be challenging, particularly when a condition has progressed from acute to chronic stages (Figure 1-13). Quantitative sensory testing (QST) refers to a set of neurologic assessments that expands upon the classic neurologic examination, providing objective or “quantitative” measures of various sensory modalities for the purpose of identifying altered neurophysiologic processing.²⁹⁰ Although QST is not considered a diagnostic test for a

particular disease entity, this set of tools may be valuable in the mechanism-based diagnosis of pain.²⁹¹ Diagnosis, by definition, directs treatment. Therefore, identifying aberrant pain mechanisms and applying interventions accordingly may allow for more effective management strategies for acute and chronic painful conditions. QST may identify both “negative” (diminished neural function) and “positive” (heightened neural function) signs.²⁹² Standardized QST performed by trained examiners has been found to have good test–retest (>75%) and interobserver reliability over 2 days.²⁹³ The German Research Network on Neuropathic Pain (DFNS) has developed a standardized battery of tests for the identification of neuropathic pain.²⁹⁰ This protocol, as well as others, provides a reference for the continuing development of QST tools. These tools apply noxious and nonnoxious stimuli to assess the function of cutaneous and deep tissue neural receptors. Measures can be considered “static,” representing the present, nonprovoked state of the nervous system, or “dynamic,” where a painful stimulus is applied in a specific manner to facilitate nociceptive processing. QST measures can be grouped as follows:

Figure 1-13. Peripheral and central sensitization. A, Injury to the knee joint. B, Nociceptive response to the injury. C, Peripheral sensitization. D, Secondary hyperalgesia. E1-E4, Quantitative sensory testing to differentiate peripheral and central sensitization.

1. MECHANICAL OR TACTILE DETECTION THRESHOLD

Cutaneous mechanical or tactile detection threshold is usually assessed with Von Frey hairs

or Semmes-Weinstein monofilaments, which are graduated in pliability such that known quantities of varying degrees of force (commonly 0.07-0.4 g of force) are applied through the tips of the monofilaments (rounded tip, 0.5 mm in diameter). The monofilament is applied slowly until the filament bows slightly. The stimulus is maintained for approximately 1.5 seconds (Figure 1-14). The most common form of testing used is the method of limits: different threshold determinations are made with a series of ascending and descending stimulus intensities. The subject is instructed to close the eyes during the test procedure and to indicate a stimulus in the test site is perceived. By calculating the geometric mean of these series (usually 5), the mean threshold value is determined.²⁹⁰

Figure 1-14. Mechanical detection threshold is measured with a standardized set of monofilaments that exert forces upon bending between 0.25 and 512 mN. The contact area of monofilaments is rounded to avoid sharp edges that would facilitate nociceptor activation. Using the “method of limits,” five threshold determinations were made, each with a series of ascending and descending stimulus intensities. The final threshold was the geometric mean of these five series.

2. VIBRATION DETECTION THRESHOLD

The ability to perceive vibration is assessed either by applying an increasing or decreasing amplitude of vibratory stimulus. The biothesiometer delivers vibration via an oscillating vibratory tip (13 mm cylinder) at a frequency of 100 Hz at the site of application, which typically is a bony prominence. Vibration amplitude is increased by 1 V/s at the site until the participant perceives the vibration sensation.²⁹⁴ Excellent intrarater and test–retest reliability has been reported.²⁹⁵ The DFNS protocol suggests the use of a Rydel–Seiffer tuning fork (64 Hz, 8/8 scale) placed over a bony prominence (Figure 1-15). Vibration threshold is determined when the perception of vibration is extinguished as the vibratory amplitude diminishes.²⁹⁰ The Rydel–Seiffer tuning fork has been found to be reliable and

valid.²⁹⁶

Figure 1-15. Vibration is initiated by squeezing and quickly releasing the tines. The tuning fork is then placed on a bony prominence. Vibration Perception Threshold is determined as a disappearance threshold with three stimulus repetitions.

3. THERMAL DETECTION AND PAIN THRESHOLD

Thermal quantitative sensory measures, such as heat or cold detection thresholds, or heat pain/cold pain detection thresholds, have been used to identify lesions in somatosensory pathways. Thermal QST is commonly used in the assessment of neuropathic pain.²⁹⁷ Increased expression of cold sensing ion channels, the TRPM8 channels, has been demonstrated in an animal model of chronic nerve injury, and is believed to be a source of cold hypersensitivity.²⁹⁸ Similarly, heat hypersensitivity is thought to be mediated, in part, by increased expression of the TRPV1 channel.²⁹⁹ Warm detection threshold is defined as the first sensation of warmth, and cold detection threshold as the first sensation of cold. Heat and cold pain thresholds are defined as the change in sensation from warmth or cold to one of heat or cold pain, respectively. The most commonly used tools for thermal QST are TSA-II (MEDOC, Israel) or MSA (SOMEDIC, Sweden) equipment; however, clinicians have used an inexpensive alternative by applying the end of warm or cold objects such as test tubes to the skin. These measures, however, provide only a gross assessment of thermal sensitivity.

4. MECHANICAL PAIN THRESHOLD

Cutaneous mechanical pain threshold is assessed using custom-made weighted pinprick stimuli as a set of different pinprick mechanical stimulators with fixed stimulus intensities (flat contact area: 0.2 mm diameter). The stimulators are usually applied at a rate of 2 seconds on, 2 seconds off in an ascending and descending order, determining which of the stimuli are perceived as painful. The final threshold is the geometric mean of five series of ascending and descending stimuli.

4.1. Mechanical Pain Sensitivity

Deep tissue mechanical pain sensitivity is commonly assessed via pressure pain thresholds, measured with an algometer (Figure 1-16). Pressure is applied with the algometer typically via a 1-cm² probe, which preferentially stimulates deep tissue, such as muscle, tendon or joints, rather than cutaneous receptors.³⁰⁰ The algometer is applied perpendicular to the tissue at a constant rate of approximately 30 kPa/s. Subjects are instructed to press a switch when the sensation changes from pressure to pain. The average of three trials is usually calculated. A 30-second resting period is allowed between each measure to avoid temporal summation. The reliability of pressure algometry has been found to be high (ICC 0.91, 95%CI 0.82-0.97).³⁰¹ Pressure pain tolerance, which is less commonly reported in the research literature, may be measured by determining the maximal pressure stimulus that is tolerated.³⁰²

Figure 1-16. Pressure pain threshold is determined using an algometer with a probe area of 1 cm². Three trials of ascending stimulus intensity are applied with a slowly increasing ramp of 50 kPa/s. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

Allodynia

Tactile or cutaneous mechanical allodynia is not uncommon in musculoskeletal and nonmusculoskeletal conditions and is defined as the evocation of pain with the application of a nonnoxious stimulus.³⁰³ Dynamic mechanical pain sensitivity of the skin is determined by slowly brushing the skin with a light tactile stimulus, such as a Q-tip, a soft brush, or cotton ball. These devices exert small forces on the skin, specifically, cotton wool (3 mN), Q-tip (100 mN), and standardized brush (Somedic, Sweden: 200-400 mN).³⁰⁴ Typically, the examiner applies one of three tactile stimuli to an area of at least a 2-cm-long skin area of an individual over a period of about 2 seconds. All stimuli should be applied with an interstimulus interval of 10 seconds, to avoid temporal summation.

5. DYNAMIC MEASURES OF CENTRAL NOCICEPTIVE SENSITIVITY

Temporal summation is the clinical correlate of the neurophysiologic phenomenon of windup, which is defined as an escalation of central nociceptive excitability. In an individual with chronic pain, where central nociceptive processing is heightened, the slope of this increasing neural excitability is steeper. Temporal summation is produced by repetitive high threshold C- and/or A δ -fiber stimulation applied at a frequency of less than 3 Hz. Subjective measures of pain are collected at specific intervals.³⁰³

Conditioned pain modulation examines the ability of inhibitory descending pain mechanisms to dampen pain. A baseline measure of pain, such as the pressure pain threshold, is established before and after the application of a conditioning stimulus, such as cold pain or ischemic pain, at a distant site. The conditioning stimulus should trigger descending inhibitory mechanisms. In a normal response, the test stimulus is perceived as less painful following the application of the painful conditioning stimulus. Pain modulation is a dynamic process, adapting to incoming nociceptive information as needed. When these mechanisms are impaired, the perception of the test stimulus is unchanged or worsened.³⁰³

6. QUANTITATIVE SENSORY TESTING AND TRIGGER POINTS

As an example, a recent study compared several QST, including thermal detection threshold, thermal pain thresholds, mechanical detection thresholds, mechanical pain thresholds, vibration detection thresholds, and pressure pain thresholds between latent TrPs and its referred pain area in the extensor radialis carpi brevis muscle and contralateral mirror sites.³⁰⁵ This study found that latent TrPs showed mechanical hyperesthesia, pressure pain hyperalgesia, and vibration hypoesthesia when compared with a contralateral mirror non-TrP, whereas the referred pain area showed pinprick and vibration hypoesthesia compared with the contralateral mirror nonreferred pain area. Interestingly, thermal pain and detection thresholds were not different between TrP/contralateral mirror point and their respectively referred pain areas, suggesting that myofascial pain is mostly related to hyperalgesia to pressure pain.

MYOFASCIAL PAIN

As Wall and Woolf established, muscle nociceptive afferents are very effective in inducing neuroplastic changes in the spinal DH.³⁰⁶ Similar to other pain syndromes, myofascial pain activates specific cortical structures, including the anterior cingulate gyrus.^{307, 308} In chronic pain conditions, many parts of the brain are involved, and it has been suggested that “the brain is enslaved by pain.”¹²⁸ Many of the pain mechanisms described in this chapter apply to myofascial pain, but in addition to contributing to pain, TrPs have significant implications for motor function, movement patterns, and range of motion.^{101, 102} In clinical practice, pain science, biomechanics, and clinical reasoning should be combined to achieve the optimal outcome.³⁰⁹

1. A BRIEF HISTORICAL REVIEW

Travell is commonly considered as the first physician to focus on myofascial pain and TrPs, although several others had already described similar phenomena many years earlier as reported by Simons and by Baldry.^{310–314} In 1940, Steindler introduced the term “trigger point,”³¹⁵ which Travell and Rinzler modified into “myofascial trigger point.”³¹⁶ Travell was strongly influenced by the work of Kellgren, a British rheumatologist affiliated with the University College Hospital in London, who published a series of papers on referred pain from muscles.^{317–320} In 1952, Travell and Rinzler described typical referred pain patterns from 32 muscles,³¹⁶ followed by many other papers,^{321–333} and eventually, the publication of the Trigger Point Manual, coauthored by Simons.^{4, 5, 49} The Trigger Point Manual has been translated into many other languages.

In 1981, Simons and Travell conceptualized the “energy crisis hypothesis,” which assumed that trauma and subsequent damage to the sarcoplasmic reticulum or the muscle cell membrane were ultimately responsible for the development of TrPs.³²¹ Damage would lead to an increase in intracellular Ca^{2+} concentration, increased activation of actin and myosin, a relative shortage of ATP, and an impaired calcium pump, which, in turn, would increase the intracellular calcium concentration even more, perpetuating the cycle. The energy crisis hypothesis was later incorporated into the integrated TrP hypothesis, which remains the most accepted and often cited hypothesis. As with most scientific explorations, the hypothesis has been modified and expanded several times and new hypotheses have been suggested.^{63–72, 140} This chapter introduces components of the integrated TrP hypothesis. Considering the complexity of this information, it will be extensively reviewed in more detail in Chapter 2.

2. IDENTIFYING TAUT BANDS AND TRIGGER POINTS

By definition, TrPs are located within taut bands, which are discrete bands of contracted muscle fibers that can be palpated, and visualized with sonography and magnetic resonance imaging, especially when combined with elastography.^{334–345} Older studies did not show great inter- and intrarater reliability^{346–349}; however, recent studies have demonstrated that taut bands and TrPs can be palpated reliably.^{20, 350–360}

When comparing the TrP region with the surrounding tissue, vibration amplitudes assessed with spectral Doppler were on average 27% lower,³³⁷ which implies a greater than normal degree of stiffness compared with normal muscle tissue.³³⁶ The mechanism for the formation of muscle taut band is not yet completely explained, but it is likely that when a muscle is overloaded, in other words, when an applied load exceeds the capability of the muscle to respond adequately, taut bands may develop, particularly following unusual or excessive eccentric or concentric loading.^{63,140} The formation of TrPs has been documented in computer operators and musicians, among others,^{361–363} where submaximal contractions cause smaller motor units to be recruited before larger motor units and derecruited last without any substitution.^{361,362} This has been described as the Cinderella Hypothesis with the additional application of Henneman's size principle.^{364–367}

3. THE INTEGRATED HYPOTHESIS

3.1. Introduction

According to the integrated TrP hypothesis, abnormal depolarization of the postjunctional membrane of motor endplates may cause a localized hypoxic energy crisis associated with sensory and autonomic reflex arcs sustained by complex sensitization mechanisms.⁶⁵ Qerama et al described higher pain intensities and pain features similar to TrPs when noxious stimuli were applied to motor endplate areas compared with silent muscle sites.³⁶⁸

The Role of the Motor Endplate

The integrated TrP hypothesis postulates that TrPs are linked to dysfunctional motor endplates. Normally, when a nerve impulse from an alpha-motor neuron reaches the motor nerve terminal orthodromically, it will open voltage-gated Na⁺ channels, which triggers an influx of Na⁺ that depolarizes the terminal membrane and opens voltage-gated P-type Ca²⁺ channels. After Ca²⁺ enters the cell, a quantal, but graded, release occurs from the nerve terminal into the synaptic cleft of approximately 100 acetylcholine(ACh)-containing synaptic vesicles, ATP, 5HT, glutamate, and CGRP, among others (Figure 1-17).^{369,370} Inhibitory neuronal receptors, including muscarinic, alpha 2- and beta-adrenoceptors, nitric oxide (NO) receptors, and purinergic P2Y receptors, among others, prevent an excessive release of ACh release,³⁶⁹ and under normal circumstances, these inhibitory mechanisms should prevent the development of persistent contractures as seen in myofascial pain. The quantal ACh release is also modulated through second-messenger systems involving PKA and PKC. The neurotransmitter adenosine synchronizes the release of quantal release of ACh. A product of the breakdown of adenosine 5' triphosphate, it acts at the inhibitory adenosine A1 and facilitatory A2a receptors. The activation of A1 receptors reduces the number of ACh molecules released in each quantum. An increase of intracellular Ca²⁺ in the nerve terminal activates the exocytotic process that is mediated by A2a receptors.

Figure 1-17. The neuropharmacology of cholinergic synaptic transmission. Sites on transmitter receptors can bind either the transmitter itself (ACh), an agonist that mimics the transmitter, or an antagonist that blocks the effects of the transmitter and agonists. (From Bear MF, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016.)

With a quantal release, ACh crosses the synaptic cleft following exocytosis and binds to acetylcholine receptors (AChRs) on the motor endplate. Acetylcholine is almost immediately partially diffused and partially hydrolyzed by acetylcholine esterase (AChE) into acetate and choline. The latter is reabsorbed into the nerve terminal, where, by combining choline and acetyl co-enzyme A from the mitochondria, it is synthesized into ACh via acetyltransferase. The release of ACh is modulated by the concentration of AChE (Figure 1-17). A soluble form of AChE prevents ACh from reaching the receptors and a second source, found within the synaptic clefts, removes ACh from the receptors binding sites. The inhibition of AChE will cause an accumulation of ACh in the synaptic cleft, which may stimulate motor nerve endings and tonically activate nAChRs (Figure 1-18). CGRP and an acidic environment also inhibit AChE. Following stimulation by ACh, nAChRs are temporarily inhibited.³⁷¹ The synthesis of AChE and nAChR involves ATP through P2Y1 nucleotide receptors.³⁷² The inhibition of AChE may also cause an increase of intracellular levels of Ca^{2+} , which likely contributes to the formation of taut bands. When Ca^{2+} is not removed from the cytosol, actin–myosin cross-bridges would remain. Removing Ca^{2+} by reuptake into the sarcoplasmic reticulum is an energy demanding process, which occurs via the Na^+/K^+ -ATPase (sarcoendoplasmic reticulum ATPase) system.

Figure 1-18. The life cycle of acetylcholine (ACh).

Jafri speculated that ROS may be intricately involved in the TrP etiology.⁶⁶ He maintains that the role of Ca^{2+} has been undervalued. Although this will be discussed in more detail in Chapter 2, Jafri hypothesized that mechanical stress can trigger an excessive release of Ca^{2+} in muscles through so-called X-ROS signaling. Mechanical deformation of the microtubule network can activate NOX_2 , which would produce ROS. The ROS oxidizes ryanodine receptors, leading to increases in Ca^{2+} release from the sarcoplasmic reticulum. The Ca^{2+} mobilization resulting from mechanical stretch through this pathway is referred to as X-ROS signaling. In skeletal muscles, X-ROS sensitizes Ca^{2+} -permeable sarcolemmal TRP channels, which may be a source of nociceptive input and inflammatory pain. Activating the TRPV1 receptor leads to a quick increase in intracellular Ca^{2+} concentrations. Jafri suggested that myofascial pain is likely due to a combined activation of several ligand-gated ion channels, including the TRPV1 receptor, ASIC3, BK, and purinergic receptors, among others.⁶⁶

The nonquantal release does not depend on activation via the alpha-motor neuron and

functions more like a fine regulator in maintaining several functional properties of skeletal muscles and various neurotrophic functions of the endplate. It is plausible that especially the nonquantal release of ACh is involved with creating taut bands seen in myofascial pain. Several neurotransmitters play a role in the regulation of ACh release. Presynaptic ATP blocks the release of quantal and nonquantal ACh. Quantal ACh is blocked through purinergic P2Y receptors, but the inhibition is also redox-dependent. A decrease in presynaptic ATP increases the release of nonquantal ACh. For example, the purinergic receptor antagonist suramin not only blocks ATP, but also inhibits NO synthase. Both events increase the release of nonquantal ACh. The inhibitory effect of ATP on the nonquantal release of ACh occurs through phospholipase C via metabotropic P2Y purinergic receptors.³⁷³ Noteworthy is a recent rodent study that demonstrated that dry needling does reduce the levels of ACh and AChR, while increasing AChE.³⁷⁴

There are many possible mechanisms leading to an excessive quantal or nonquantal release of ACh, such as increased muscle tension, an increased sensitivity of nAChR, AChE insufficiency, hypoxia, a low pH, a shortage of ATP, certain genetic mutations, drugs, increased levels of CGRP and diisopropyl fluorophosphate, or organophosphate pesticides.^{63, 64, 375–377} CGRP plays a key role in the regulation of ACh at the motor endplate in addition to its many other functions, such as microvascular vasodilation in wound healing, prevention of ischemia, and several autonomic and immune functions.³⁷⁸ CGRP and its receptors are widely expressed in the central and peripheral nervous system. CGRP is released from the trigeminal ganglion and from trigeminal nerves within the dura and contributes to peripheral sensitization.³⁷⁹ CGRP Type I is also produced in the cell body of motor neurons in the ventral horn of the spinal cord and is excreted via an axoplasmatic transport mechanism. It stimulates the phosphorylation of ACh receptors, which prolongs their sensitivity to ACh.³⁸⁰ Furthermore, it promotes the release of ACh and inhibits AChE. CGRP is found in higher concentrations in the immediate vicinity of active TrP.^{381–383} A2a receptors near motor endplates also contribute to the facilitatory effect of CGRP on the release of ACh.

According to the integrated TrP hypothesis, the excessive amount of ACh in the synaptic cleft will cause constant depolarizations of the postsynaptic cell, trigger miniature endplate potentials, and produce action potentials, that travels along the T-tubules toward the sarcoplasmic reticulum. Persistent contractures are likely to compromise local blood vessels, reduce the local oxygen supply, cause hypoxia, a lowered pH, and hypoperfusion, which, in turn, reinforce the excessive release of ACh and contribute to muscle pain and dysfunction.^{140, 384} Trigger point hypoxia has been confirmed in German and American research studies.^{385, 386} The combination of hypoxia and an increased metabolic demand results in a local energy shortage and a local shortage of ATP,⁶⁵ in addition to triggering an increased release of ACh at the neuromuscular junction and a decrease in the tissue pH, which, once again, will activate TRPV channels and ASICs and trigger pain, hyperalgesia, and central sensitization without inflammation or any damage or trauma to the muscle.^{236, 237, 387–392}

A 1993 paper by Hubbard et al of spontaneous electromyographic (EMG) activity in the vicinity of TrPs triggered a new line of research into the role of motor endplates.³⁹³ Hubbard et al described a low-amplitude constant background EMG activity of 50 μ V and an intermittent higher-amplitude spike-like of 100 to 700 μ V. They assumed a pertinent role for muscle spindles, but subsequent human and animal research demonstrated that the observed EMG activity was, in fact, endplate noise caused by an excess of ACh at the neuromuscular junction.^{60, 61, 394–402} In fact, the prevalence of endplate noise elicited from a TrP was directly correlated with irritability, pain intensity, and pressure pain thresholds.⁶⁰ Nevertheless, TrPs feature a reduced reflex threshold and a higher reflex amplitude, which could be related to a greater density or excitability of muscle spindle afferents.⁵³ It appears that TrP pain and tenderness are closely associated with sustained focal ischemia and muscle cramps within muscle taut bands, possibly because cramps may induce intramuscular hypoxia, increased concentrations of algogenic mediators, direct mechanical stimulation of nociceptors, and eventually, the experience of pain.⁴⁰² The intramuscular and surface EMG activity recorded from a TrP showed that the electrical signal was similar to a muscle cramp potential.⁵⁴ Dry needling, laser, calcium blockers, and botulinum toxin injections were found to be able to reduce the degree of endplate noise.^{374, 398, 403–407}

The Biochemical Milieu of Trigger Points

Human studies at the US National Institutes of Health have identified a unique biochemical milieu of active TrPs with elevated levels of CGRP, substance P, 5-HT, NE, BK, PG, tumor necrosis factor- α (TNF- α), interleukins IL-1 β , IL-6, and IL-8, as well as a significantly lowered pH.^{381, 383, 408} Hsieh et al studied the biochemical environment in rabbits and confirmed elevated levels of multiple other chemicals, such as beta-endorphin, substance P, TNF- α , cyclo-oxygenase-2 (COX-2), hypoxia-inducible factor 1- α , inducible nitric oxide synthase, and vascular endothelial growth factor.^{409, 410} The elevated levels of many of these substances near active TrPs are consistent with biochemical pathways involved in tissue injury and inflammation.^{382, 383}

The orthodromic and antidromic release of these chemicals is enhanced in response to nociceptor activation, for example by protons and BK.⁴¹¹ It should come as no surprise that each of these chemicals has specific receptors and that their increased concentrations will have a potential impact on pain and function. The low pH, which often is the result of ischemia and hypoxia, will activate ASIC and TRPV receptors, as discussed previously. A further complicating factor is that many of these substances reinforce each other. BK stimulates the release of TNF- α , which, in turn, facilitates the release of IL-1 β and IL-6. The interleukins stimulate the COX nociceptive pathway, which leads to the production of PGs.^{412, 413} TNF- α produces a time- and dose-dependent muscle hyperalgesia, which is completely reversed by systemic treatment with the nonopioid analgesic metamizol.⁴¹⁴ BK, 5-HT, and PG interact at many levels at the vanilloid receptors and synergistically may cause local muscle pain.⁴¹⁵ An injection of the combination of BK and 5-HT into the temporalis muscle of healthy volunteers caused more pain than when each

stimulant was injected alone.⁴¹⁶

Substance P causes mast cell degranulation with the subsequent release of histamine, 5-HT, and upregulation of proinflammatory cytokines, including TNF-alpha and IL-6, and anti-inflammatory cytokines, including IL-4 and IL-10. TNF-alpha is the only cytokine restored in the mast cell and is released immediately following mast cell degranulation.^{417,418} Increased levels of NE suggest involvement of the autonomic nervous system in myofascial pain, as suggested by Ge et al.⁴¹⁹ The local or systemic administration of the alpha-adrenergic antagonist phentolamine to TrPs caused an immediate reduction in endplate noise.^{420,421} In other studies, sympathetic blockers reduced TrP and tender point pain sensitivity.⁴²²⁻⁴²⁴ The specific pathway is not known, but perhaps alpha- and beta-adrenergic receptors at the endplate provide a potential mechanism.^{63,425,426} TNF-alpha can also contribute to an autonomic pathway by stimulating the release of IL-8,⁴²⁷ which can induce a dose- and time-dependent mechanical hypernociception.⁴²⁸ Hence, elevated levels of IL-8 may mediate inflammatory hypernociception, muscle tenderness, and pain in active TrPs. It is conceivable that the increased concentration of chemical substances near active TrPs may contribute to an increased static fusimotor drive to muscle spindles or to increased muscle spindle sensitivity.⁴²⁹

Dry needling and laser can reduce the levels of the substances found in the immediate TrP environment, especially after eliciting LTRs with dry needling, but excessive treatment increased the concentrations.^{409,410,430} An LTR is thought to be a spinal cord reflex, and can perhaps best be described as a sudden contraction of muscle fibers within a taut band.^{431,432} There is some preliminary evidence that the number of LTRs may be related to the irritability of a TrP,⁵⁷ likely due to sensitization of muscle nociceptors by BL, 5-HT, and PG, among others. Recently, several authors have questioned whether eliciting LTRs is necessary or even desirable,⁴³³⁻⁴³⁵ whereas others have strongly advocated in favor of eliciting LTRs.⁴³¹

Pain and Trigger Points

One of the most important contributions of Travell was her attention to referred pain from TrPs.^{5,49,316,328} Familiarity with common referred pain patterns is critical in clinical practice, and a lack of awareness may lead to an incorrect diagnosis, a less than optimal treatment approach, unnecessary surgery, immobilization, bedrest, and medicalization. Referred pain, also known as secondary hyperalgesia, is a common phenomenon whereby pain is experienced in a different region than the source of pain.^{436,437} Referred pain associated with TrPs is very common and seen with nearly all myofascial pain problems.^{13,27,57,70,152,170,438-457} Referred pain can be elicited from many different structures and can be perceived in any region of the body. The size of the referred pain area is variable and is dependent upon pain-induced changes in central somatosensory maps.^{318,458} As mentioned before, active TrPs have larger referred pain areas than latent TrPs.⁵⁷ Latent TrPs provide nociceptive input into the DH, and as such, they also feature

referred pain.^{55, 459–463} The size of the referred pain area is correlated with the intensity and duration of muscle pain, which supports the presence of a central sensitization phenomenon maintained by peripheral sensitization input.⁴⁵²

Muscle referred pain occurs usually in a central to peripheral direction, but some muscles have referred pain patterns that may develop in a caudal and cranial direction (Figure 1-19). Muscle referred pain is often described as deep, diffuse, burning, tightening, or pressing pain, which differentiates it from neuropathic or cutaneous pain. Other symptoms, such as numbness, coldness, stiffness, weakness, fatigue, or musculoskeletal motor dysfunction, may also be associated with muscle pain, which suggests that perhaps the term “referred sensation” would be more appropriate.⁵² Muscle referred pain patterns are similar to joint referred pain patterns. Historically, several models of referred pain have been developed, including the convergent-projection theory, the convergence-facilitation theory, the axon-reflex theory, the thalamic-convergence theory, and the central hyperexcitability theory.^{464–467}

Figure 1-19. Infraspinatus pain referral pattern.

The exact mechanisms of referred pain are still not completely understood, but there is enough data to support that “muscle referred pain is a process of central sensitization, which is mediated by a peripheral activity and sensitization, and which can be facilitated by sympathetic activity and dysfunctional descending inhibition.”^{419,468} The central hyperexcitability theory is consistent with most of the characteristics of muscle and fascia referred pain. The degree of referred pain is dependent on the stimulus. Often, the onset of referred pain is more delayed following a stimulus than the onset of local pain. Animal models have shown that muscle referred pain, which can appear within minutes, features an expansion of receptive fields and sensitization.^{467,469,470} Mense suggested that the appearance of new receptive fields may indicate that latent convergent afferents on the DH neuron are opened by noxious stimuli from muscle tissues, which could induce the referred

pain.⁴³⁷ Trigger points are more effective in inducing referred pain and other neuroplastic changes in the DH neurons than non-TrPs regions.⁴⁷¹

Considering the available evidence, TrPs function as persistent sources of nociceptive input and contribute to peripheral and central sensitization.^{26,27} Arendt-Nielsen et al provided evidence that experimentally induced muscle pain is able to impair DNIC mechanisms, supporting an important role of muscle tissues in chronic pain.⁴⁷² Mechanical stimulation of latent TrPs can induce central sensitization in healthy subjects leading to pressure hypersensitivity in extrasegmental tissues.⁵⁵ There is also some evidence that central sensitization can increase the sensitivity of TrPs,^{67,68,473} but it is more likely that TrPs induce sensitization, as latent TrPs are present in healthy individuals without evidence of central sensitization. Persistent pain, for example, in patients with fibromyalgia or in experimental conditions, is frequently maintained by persistent nociceptive input from muscles.^{151,152,441,474,475} The pain associated with TrPs and TrP therapies, such as manual compression and dry needling, is not related to particular anatomic lesions, but is the result of physiologic changes and peripheral and central sensitization.²⁷ Treatments directed at TrPs seem to reverse peripheral and central sensitization.^{28,136,476,477} The underlying mechanisms of myofascial pain and TrPs will be further explored in Chapter 2.

Trigger Point Neurophysiology

Robert D. Gerwin

1. INTRODUCTION

The myofascial trigger point (TrP) is the accepted basis for the local and referred pain of the myofascial pain syndrome (MPS). Despite recent studies of the TrP, the actual mechanisms of the development and resolution of the TrP remain speculative. Simons' Integrated Hypothesis painted a broad picture of the mechanism by which the TrP taut band and TrP-induced pain developed, but left out the necessary details by which the TrP actually occurs.¹ More details were offered by Gerwin et al,² but many details of the taut band, the TrP, and the MPS remain obscure. Since then, others have summarized or added to these hypotheses, particularly Bron and Dommerholt.³ However, these proposals have been accompanied in recent years by new studies that have confirmed some aspects of the hypotheses, whereas others remain completely speculative. Among unanswered questions are the mechanism(s) by which the sympathetic nervous system (SNS) influences the taut band, the mechanism by which the taut band develops and is maintained, the mechanism leading to endplate noise, the mechanism of the local twitch response, and the mechanism by which the TrP is resolved. Moreover, the role that the fascia tissue plays in the creation and maintenance of TrPs remains to be explicated, which is addressed in Chapter 3. Finally, the question as to why the TrP is transient in some people, and persists in others, has not been adequately explored. Many of the premises have been introduced in Chapter 1. There will be some overlap, but the combination of the two chapters will provide a comprehensive review of the current thinking.

This discussion will briefly review what is known about the development of the TrP taut band, as that seems to be the first clinical sign of the TrP. Then, the role of functional changes in the neuromuscular junction (NMJ) will be explored. The role of the alpha-adrenergic SNS will also be considered. Calcium (Ca^{2+}) is required for cross-bridging to occur between actin and myosin molecules to produce muscle contraction. Therefore, perturbations in the excitation-contraction coupling (ECC) mechanism will be discussed,

in particular the possibility that a polymorphism affecting a major calcium ion channel could play a role in the maintenance of the taut band (TB). As adenosine triphosphate (ATP) is required for the removal of Ca^{2+} from the cytosol to reverse actin–myosin cross-bridging, the effect of changes in ATP concentration will be reviewed, especially in relationship to another ion channel polymorphism. Furthermore, the beta-adrenergic SNS also modulates cytosolic Ca^{2+} levels, and its role must be explored. In the end, mutations leading to polymorphism associated with ion channel function, important in regulating cytosolic Ca^{2+} concentrations ($[\text{Ca}^{2+}]_c$), are considered a major possibility for the development and maintenance of the taut band in certain individuals.

2. EVIDENCE-BASED PRESENT UNDERSTANDING OF THE TRIGGER POINT

Segmental Sarcomere Contraction

The observation that discrete, tender, muscle bands develop led to the concept that there is an underlying localized intense contraction of sarcomeres that can be felt as a discrete knot in the muscle. This concept was given impetus by the reexamination of a photomicrograph published by Simons and Stolov of canine muscle showing a region of intense sarcomere contraction under a structure that could possibly be an NMJ⁴ (Figure 2-1). This observation led to efforts to replicate focal zones of sarcomere contraction in the experimental animal, primarily by using an anticholinesterase (AChE) inhibitor, an effort that has not been wholly successful.⁵ Nevertheless, the concept of segmental sarcomere contraction has given rise to a search for mechanisms that will cause sustained sarcomere contraction and that are consistent with clinical observations. There has not been a published study showing that zones of intense sarcomere contraction occur at TrP sites in either humans or animals.

Figure 2-1. Longitudinal section of an example of the contraction knots seen in biopsies of canine muscles, in this case the gracilis. An exquisitely tender spot in a taut band of the muscle was selected as the biopsy site. These are two essential TrP criteria. The striations (corresponding to sarcomere length) indicate severe contracture of the approximately 100 sarcomeres in the knot section of the muscle fiber. The sarcomeres on both sides of the knot show compensatory elongation compared with the normally spaced sarcomeres in the muscle fibers running across the bottom of the figure. The fiber diameter is markedly increased in the region of the knot and abnormally decreased on either side of it. The irregularity of the sarcolemma along the upper border of the fiber (in the center of the contraction knot) may represent an endplate. The distortion of the sarcomere alignment in adjacent muscle fibers represents sheer stresses in those fibers that may, in time, play a part in the propagation of this dysfunction to neighboring muscle fibers.

Trigger Point Electrophysiology

There is a characteristic electromyographic (EMG) signature of the active TrP that is used as a marker for the TrP. It is a combination of low-amplitude fast activity consistent with miniature endplate potentials (MEPPs), though of higher frequency than is usually seen with MEPPs, and intermittent, higher-amplitude spike activity called endplate spikes (EPSs) that generally have an initial electrical negativity. These characteristic discharges were first reported by Hubbard and Berkoff,⁶ and subsequently studied in detail by Simons et al,^{7,8} and also by Couppé et al.⁹ The spontaneous electrical activity (SEA) of the TrP (Figure 2-2) described by Hubbard and Berkoff was confined to a 1 to 2 mm diameter locus, and was of a rather constant low-amplitude discharge of about 50 μ m or less, punctuated by higher-amplitude spikes that were about 50 to 100 μ m. The SEA is present in the resting muscle as shown by EMG recording of adjacent muscle outside the taut

band. Couppé et al reported the TrP electrical discharges to be characteristic of endplate noise with both MEPPs of low voltage, monophasic, negative potentials, and EPS of up to 600 μV amplitude, initially negative and irregular in nature. These authors associated the electrical activity with motor endplate activity. Ojala et al reported EPS at TrPs, but also found complex repetitive discharges (CRDs) in some TrPs.¹⁰ Moreover, they reported that EPSs were not confined to TrPs. SEA is most prominent in the taut band at the TrP zone, has a restricted range in the taut band, and is long-lasting and persistent.

Figure 2-2. Typical recording of the spontaneous electrical activity and spikes recorded from an active locus of a TrP at two different sweep speeds. A, Recording at the same slow sweep speed of 100 msec/div used by Hubbard and Berkoff⁶ to report this electrical activity. Only spikes of unknown initial polarity are identifiable. B, A similar amplification but a 10-times higher sweep speed of 10 msec/div that was used in subsequent studies by others^{7,8} who also have observed the low-amplitude noise component as well as the polarity of initial deflection of the spikes from active loci. This additional information is of critical importance for understanding the source and nature of these potentials.

The mechanism of TrP SEA is still unknown but has been attributed to a dysfunctional NMJ and motor endplate,¹ although Hubbard and Berkoff⁶ and later Partanen et al¹¹ were of the opinion that the source of the activity was the muscle spindle, and that the spindle was the anatomic site of the dysfunction causing the TrP and the taut band itself. This will be discussed in detail later in this section. In any event, the high frequency of the MEPP-like activity begs explanation.

3. THE NEUROMUSCULAR JUNCTION

Trigger Point Taut Band

The discrete TrP taut band in muscle is a dense band of muscle that was demonstrated on ultrasound by Gerwin and Duranleau in 1997,¹² and then later with modern techniques and in much greater clarity by Sikdar et al.¹³ Increased synaptic efficiency at the NMJ could cause greater motor endplate activation, but should not lead to persistent contraction because of other regulatory mechanisms that stop excessive acetylcholine (ACh) release

from the motor nerve. Concentration of ACh at the motor endplate, the key factor in determining motor endplate activity, can be modulated by any one of several mechanisms. A brief review of the way in which ACh is released and then binds with the acetylcholine receptor (AChR) will form the basis for understanding the regulatory mechanisms that control ACh at the motor endplate.

Orthodromic Axon-Stimulus-Evoked Release

Orthodromic axon-stimulus-evoked release of ACh at the NMJ is a quantal but graded (not an “all-or-none”) release that results in muscle contraction through depolarization of the muscle membrane at the motor endplate. Acetylcholine, released from the motor nerve terminal, crosses the synaptic cleft and binds to AChR on the motor endplate (Figure 2-3). A sufficient number of ACh molecules binding to AChR on the motor endplate will depolarize the muscle membrane, generating an action potential that travels down membrane invaginations called T-tubules to the dihydropyridine receptor (DHPR) that is located in the T-tubule membrane (Figure 2-4A and B). The intermolecular signal is transmitted from L-type Ca^{2+} channels in the plasma membrane to a ryanodine receptor (RyR) calcium channel that is situated 10/nm away.¹⁴ The DHPR physically blocks the RyR calcium channel situated in the sarcoplasmic reticulum (SR). Membrane depolarization disengages DHPRs from RyRs, opening the channels and allowing the transit of Ca^{2+} from the SR into the cytosol, thus increasing the concentration of cytosolic calcium ($[\text{Ca}^{2+}]_c$).¹⁵

Figure 2-3. Neuromuscular junction. A, Neurons and muscle fibers communicate at the neuromuscular junction. B, Electrical signals travel along the axon and stimulate synaptic vesicles at its end to release acetylcholine, a neurotransmitter, into the synaptic cleft. C, Acetylcholine crosses the synaptic cleft and binds to receptors in the sarcolemma of muscle fibers, causing changes within the muscle cell that initiate muscle contraction.

Figure 2-4. A, The structure of a muscle fiber. T-tubules conduct electrical activity from the surface membrane into the depths of the muscle fiber. B, The release of Ca^{2+} from the sarcoplasmic reticulum (SR). Depolarization of the T-tubule membrane causes conformational changes in proteins that are linked to calcium channels in the SR, releasing stored Ca^{2+} into the cytosol of the muscle fiber.

Cytosolic Ca^{2+} Requirement for Muscle Contraction

Cytosolic Ca^{2+} interacts with actin and myosin to produce sarcomere shortening through cross-bridge formation, leading to contraction and shortening of the sarcomere. Actin-binding sites on myosin heads, blocked by tropomyosin (Figure 2-5A), are displaced by Ca^{2+} that binds to troponin, thereby displacing tropomyosin to expose myosin-head binding sites (Figure 2-5B). Cross-bridging links then form between actin and myosin (Figures 2-5B and 2.6). A configurational change occurs bending the myosin heads. Repeated binding, and then release, of Ca^{2+} to troponin leads to a progressive “walking” of actin molecules overlapping myosin, resulting in an increasing overlap of the two molecules. Actin, attached to sarcomere Z lines by titin, contracts the sarcomere as the actin–myosin complex is shortened (Figure 2-7). The process is terminated by the removal and reuptake of Ca^{2+} into the SR, an energy-requiring process mediated by CaATPase and ATP dependent.¹⁶

Figure 2-5. The events of muscle contraction. A, At rest, strands of tropomyosin proteins cover binding sites on actin and prevent interaction between actin and myosin. B, Action potentials release calcium into the sarcoplasm, which bind to troponin. The bound calcium deforms the tropomyosin protein, exposing actin-binding sites and allowing cross-bridges to form between the myosin heads and actin.

Figure 2-6. Sliding-filament mechanism. A, Prior to transmission of the action potential, no cross-bridges connect actin and myosin. B, Once the active sites are revealed and myosin heads bind to actin, the power stroke occurs. Synchronized movement of the myosin heads pulls the ends of the sarcomere together, shortening the muscle. C, Energy from ATP releases the myosin heads and positions them for another power stroke.

Figure 2-7. The sliding-filament model of muscle contraction. Myofibrils shorten when the

thin filaments slide toward one another on the thick filaments.

Subthreshold Depolarization

Acetylcholine molecules binding at the motor endplate in insufficient quantities to produce an AP are still able to produce a subthreshold, local, depolarization that does not result in a propagated membrane depolarization. However, a sufficient subthreshold depolarization has been shown to cause localized sarcomere contraction in cardiac muscle at regions with high concentrations of cytosolic Ca^{2+} ($[\text{Ca}^{2+}]_c$). The local cardiac myocyte contraction results in a wave of focal sarcomere contraction that travels along the muscle membrane.¹⁷ Thus, it is known that a sufficient number of ACh molecules at the motor endplate will generate an action potential that depolarizes the muscle membrane, and an insufficient number of ACh molecules can cause a localized membrane depolarization.

4. HISTOPATHOLOGY OF THE TRIGGER POINT

There is no definitive histopathologic study of TrPs. The Integrated Hypothesis presupposes a dysfunctional NMJ, giving rise to multiple, local foci of hypercontractured sarcomeres.¹ The TrP in this model is envisioned as a locus of multiple localized sarcomere contractions, more appropriately considered to be contractures (Figure 2-8). Excessive muscle work resulting in muscle overload, such as excessive eccentric contraction, is one suggested mechanism leading to TrPs. However, muscle subjected to eccentric contraction and muscle subjected to delayed onset muscle soreness syndrome, another candidate thought possibly to produce TrPs, shows disruption of sarcomeres with loss of structure, decreased or lost alpha-actinin, titin, and nebulin, and Z-disc streaming,^{18,19} but no contracture knots. Contractured sarcomeres have been found in the rat adductor longus muscle subjected to unloaded eccentric lengthening,²⁰ but only a few sarcomeres in succession were shortened, and none to the degree postulated by Simons and Travell,¹ and none with increased muscle fiber widening at the site of hypercontractured sarcomeres as seen in the one canine muscle microphotograph that has become the paradigm of the TrP.⁴ Thus, the hypothesis that there are contracture knots in muscle TrPs has not been confirmed by morphologic studies in some of the conditions thought likely to produce TrPs. The limitation of the morphologic studies is that we do not know where samples were taken from in the muscle, or whether sections were taken from TrP sites or not.

Figure 2-8. Schematic of a TrP complex of a muscle in longitudinal section. A, The TrP which is in the endplate zone and contains numerous contracture knots. B, Enlarged view of part of the TrP shows the distribution of five contracture knots and their effects on adjacent sarcomeres.

4.1. Neurotransmitters

Presynaptic Neurotransmitters

Multiple neurotransmitters are coreleased from the motor nerve ending along with ACh, substances such as ATP, calcitonin gene-related peptide (CGRP), and serotonin (5 HT). ATP is the main neurotransmitter released along with ACh.²¹ It inhibits nerve-evoked, quantal release of ACh from the nerve terminal.

Nonquantal release (NQR) of ACh is not nerve-evoked, but is a spontaneous and variable release of ACh directly through the nerve terminal membrane rather than by vesicle

exocytosis. It is thought to maintain the integrity of the skeletal muscle.²² However, if nonquantal ACh increases beyond a certain level, it is postulated that it could produce local membrane depolarization and sarcomere contraction under the motor endplate, and thus initiate the changes that result in the TrP. ATP also inhibits NQR of ACh from the motor neuron. The regulation of quantal release is mediated through Ca^{2+} influx into the motor nerve terminal through presynaptic voltage-gated calcium channels. Nonquantal regulation of ACh release is inhibited by Mg^{2+} through nitric oxide (NO) and purine pathways. However, intensive muscle contraction depletes ATP, thereby diminishing its inhibitory effect on ACh release from the nerve terminal.

4.2. Adenosine Triphosphate and the Energy Crisis Theory of Simons

The effect of ATP on the development of the TrP has been attributed to its role in Ca^{2+} reuptake into the SR.¹ However, ATP has a profound effect on NQR of ACh that may be important in TrP formation. The role of ATP and of NQR of ACh has been reviewed in detail by Vyskoc'il et al.²³ In a series of studies performed over almost 30 years, Vyskoc'il et al studied the release of ACh from nerve in muscle. They found that NQR of ACh from nerve endings provides about 90% to 98% of ACh release in the resting muscle. Nonquantal ACh release occurs directly through the nerve terminal membrane and not through vesicles as quantal release does. NQR of ACh produces MEPPs that increase in frequency directly related to an increase in nonquantal ACh release. ATP depresses nonquantal ACh release independently of $[\text{Ca}^{2+}]$. Severe muscle fatigue and hypoxia both reduce ATP concentrations and increase both nonquantal ACh release and MEPP frequency. Nonquantal ACh release occurs at the endplate region but also in the peri-endplate zone where there is less AChE. The current model for TrP formation is that local areas of muscle hypoxia occur in the TrP zone. Thus, ATP concentrations fall, and the regulatory, inhibitory effect of ATP on NQR of ACh in the resting muscle is diminished, and ACh levels in the endplate and peri-endplate regions increase, causing localized muscle membrane depolarization and localized sarcomere contraction. In other words, a fall in ATP levels increases the spontaneous release of ACh, increases the likelihood of localized sarcomere contraction, and increases the frequency of MEPPs, all of which are seen in the TrP.

4.3. Postsynaptic Effects: Acetylcholine Effects at the Motor Endplate

The MEPPs, persistent low-amplitude activity with an initial negativity, interspersed with high-amplitude discharges, EPS, found at the active TrP zone and highly localized within the taut band, has been interpreted as motor endplate activity by Simons and others.^{7, 8, 24} SEA found at the TrP, also called endplate noise, is caused by ACh binding at the motor endplate. Several possible causes of an excess of ACh at the motor end plate were summarized by Gerwin et al and others,^{2, 3} refer to Box 2-1. CGRP, coreleased with ACh, is known to facilitate the release of ACh and inhibit AChE. It also induces AChR synthesis,

thus increasing the number of receptor sites at and beyond the endplate region. Additionally, protons (H^+) that are increased in the TrP milieu inhibit AChE.²⁵

Box 2-1 Causes of excessive ACh at the motor endplate

1. Increased release of ACh from the motor nerve terminal
2. Decreased breakdown of ACh in the synaptic cleft extracellular fluid
3. Increased numbers of AChR providing binding sites for ACh
4. Decreased removal of ACh from AChRs on the motor endplate

4.4. Regulation of Acetylcholine Release From Motor Nerve Terminals by ATP

Release of ACh from the motor nerve terminal is highly regulated. Some examples will be discussed to illustrate the degree of complexity of regulatory mechanisms. A feedback mechanism involving NO reduces ACh release when the frequency of repetitive APs is too high,²⁶ thereby preventing hypercontracted muscle and cell damage. The corelease of ATP with ACh provides one such mechanism for this feedback regulation by inhibiting the release of ACh from the motor nerve terminal. The neurotransmitter adenosine, generated by the breakdown of ATP, is a modulator of presynaptic release in both peripheral and central synapses.¹⁶ Adenosine acts at adenosine receptors on the motor nerve terminal surface. The adenosine receptor A1 is inhibitory and the adenosine receptor A2a is facilitatory for the release of ACh. Adenosine synchronizes the quantal release of ACh, thereby improving synaptic efficiency. This is mediated by purinergic A1 receptors on the presynaptic nerve terminal.^{16,27} Activation of A1 receptors reduces ACh molecules released in each quantum. Adenosine receptor activity that modulates both evoked and spontaneous ACh release is dependent on the coactivity of muscarinic AChRs.²⁸ In this way, ATP has a direct inhibitory action on the release of ACh. The breakdown of ATP and decreased synthesis of ATP increases adenosine levels. Thus, lower ATP levels may correlate with higher adenosine levels. The inhibitory effect of ATP via adenosine generated by ATP breakdown is also redox dependent. Thus, the effect of ATP may be amplified by oxidative stress.²⁹ Increasing intracellular Ca^{2+} in the nerve terminal also activates the exocytotic process that is mediated by A2a receptors, further facilitating the ACh release.³⁰ In these ways, the corelease of ATP with ACh from the motor nerve terminal serves to modulate the release of ACh, preventing excess muscle contraction by a feedback loop mechanism, through inhibitory and facilitatory influences that are rate dependent.

4.5. Adenosine Receptor Activation Effect on ACh Release

Presynaptic adenosine receptors are key ACh release modulators. A1 receptor activation inhibits ACh release, and A2a receptors facilitate ACh release.^{31,32} Activation of A2a is essential for the facilitatory effect of CGRP on ACh release. A2a facilitatory effect is mediated via an external Ca^{2+} -independent mechanism that involves mobilization of Ca^{2+}

from ryanidine-sensitive internal stores, and, at high $[K^+]$, probably by modulating the L-type VDCCs which may cause the opening of the RyR, and thereby activating the exocytotic machinery, thus facilitating ACh release.

The importance of purigenic adenosine receptors is further shown by a study using mice deficient in the P_2X_2 receptor subunit which have their motor nerve terminals displaced from AChR sites, reduced density of postsynaptic junctional folds, endplate fragmentation, and muscle fiber atrophy.²⁷ Further modulation of ACh release occurs through second messenger systems involving protein kinase A and C (PKA and PKC).^{33, 34} Acetylcholine release from the motor nerve terminal is both facilitated and inhibited by various mechanisms. The exact role that any of one factor plays in the development of the TP taut band remains a fertile area for research.

5. THE MOTOR ENDPLATE

5.1. Excitation-Contraction Coupling

The contraction of muscle fibers at the NMJ is dependent on membrane depolarization and conversion of electrical activity to molecular cross-bridging and conformation change. This is accomplished through membrane invaginations called T-tubules (Figure 2-4A). Depolarization activates the DHPR that blocks the RyR and causes it to disengage from the RyR to allow the efflux of Ca^{2+} from the SR into the cytoplasm (Figure 2-4B). This process is called ECC. Membrane depolarization requires a sufficient number of ACh molecules binding to AChR. As noted earlier, subthreshold endplate activation can produce local sarcomere contraction under the endplate, but not a propagated action potential.

Acetylcholinesterase

Acetylcholinesterase (AChE) is necessary to remove ACh from AChR so that the membrane could repolarize. Acetylcholinesterase is located deep in endplate membrane clefts. There is also a soluble form of AChE in the synaptic space. Soluble AChE reduces the amount of ACh crossing the synaptic space that reach AChRs on the endplate, and endplate AChE removes ACh from the endplate binding sites (Figure 2-9). Acetylcholinesterase activity is inhibited in an acidic environment, such as that found in the TrP milieu, and by CGRP. Acetylcholinesterase inhibition increases the efficiency of ACh binding at the motor endplate, but may be deleterious, increasing intracellular $[Ca^{2+}]$ to damaging levels. It may also be one reason why the taut band forms and why TP endplate noise (EPS) are more frequent and persistent than normal endplate activity.

Figure 2-9. Motor endplate and neuromuscular junction.

5.2. Other Neurotransmitter Feedback Control Mechanisms

Adenosine triphosphate, coreleased from the motor nerve terminal with ACh, is also active at the endplate. Adenosine triphosphate stimulates, via the P_2Y_1 nucleotide receptor, the transcription genes that synthesize AChE, and the transcription genes for AChR, thus increasing the endplate expression of both AChE and AChR.³⁵ CGRP, also coreleased from the motor nerve terminal with ACh, increases the number and expands the domain of AChRs at the motor endplate. Thus, both ATP and CGRP increase the binding sites on the motor endplate, increasing the efficiency of ACh binding. The balance between the release of ACh, binding to AChR, and removal by AChE acts to control muscle contraction under normal circumstances. Normal regulatory mechanisms may become dysfunctional in a pathologic situation such as excessive muscle activity or intense muscle fatigue. The TrP is likely to be one such pathologic situation. The TrP milieu is hypoxic and acidic,²⁵ both

conditions favoring increased ACh at the endplate. The data suggest that the taut band is maintained by a continuous series of small, local subthreshold action potentials rather than by muscle stiffness independent of electrical activity.

The common feature in all of these mechanisms is the increase in ACh at the motor endplate and the increase in cytosolic Ca^{2+} . Dysfunctional RyRs can leak calcium, thereby increasing intracellular calcium, and “sick” mitochondria can also leak calcium. Ca^{2+} can also enter the cytosol from the endoplasmic reticulum (ER). Thus, there are conditions in which $[\text{Ca}^{2+}]$ may be increased that are unrelated to the evoked stimulus release of ACh, and that may serve to initiate or maintain muscle contraction. The role that these mechanisms may play in TP genesis remains speculative. One model for the role of inappropriate release of calcium through RyRs within muscle cells is malignant hyperthermia, a condition that is also characterized by persistent muscle contraction.

6. TRIGGER POINT HYPOTHESES

6.1. The Integrated Hypothesis and the Muscle Spindle Hypothesis

Simons' Integrated Hypothesis

A theory of persistent sarcomere contraction underlying the TrP phenomena that we see clinically occurring from ACh excess at endplates has some limitations. Simons' Integrated Hypothesis (Figure 2-10) postulated an energy crisis such that Ca^{2+} is not removed from the cytosol, so that muscle actin and myosin cross-bridging persist; muscle fibers, therefore, would not relax. Release of actin–myosin cross-bridging requires that Ca^{2+} is removed from the cytosol, primarily by reuptake into the SR. This energy-requiring process occurs via the Na^+/K^+ -ATPase (sarcoendoplasmic reticulum ATPase [SERCA]) system that supports influx of Ca^{2+} into the SR, thereby lowering the $[\text{Ca}^{2+}]_c$. The theory is based on several observations, refer to Box 2-2.

Figure 2-10. Integrated hypothesis. The primary dysfunction hypothesized here is an abnormal increase (by several orders of magnitude) in the production and release of acetylcholine packets from the motor nerve terminal under resting conditions. The greatly increased number of miniature endplate potentials produces endplate noise and sustained depolarization of the postjunctional membrane of the muscle fiber. This sustained depolarization could cause a continuous release and uptake of calcium ions from local sarcoplasmic reticulum and produce sustained shortening (contracture) of sarcomeres. Each of these four highlighted changes would increase energy demand. The sustained muscle

fiber shortening compresses local blood vessels, thereby reducing the nutrient and oxygen supplies that normally meet the energy demands of this region. The increased energy demand in the face of an impaired energy supply would produce a local energy crisis, which leads to the release of sensitizing substances that could interact with autonomic and sensory (some nociceptive) nerves traversing that region. Subsequent release of neuroactive substances could in turn contribute to excessive acetylcholine release from the nerve terminal, completing what then becomes a self-sustaining vicious cycle.

Box 2-2 Theory of persistent sarcomere contractures

1. SEA or EPS at the TrP zone
2. The TrP zone is ischemic
3. The single photomicrograph of the canine muscle (Figure 2-1) showing contracted sarcomeres

However, problems of interpretation and lack of evidence remain. There is controversy over the origin of endplate noise/spikes. Elevated levels of ACh at trigger sites in the resting muscle have never been measured, and so have never been found to be increased. There has never been a definitive histologic demonstration that hypercontracted sarcomeres are actually associated with TPs, or even that they are found in human muscle.

The Muscle Spindle Hypothesis

The argument supporting the role of the muscle spindle in the generation of TrPs is summarized by Partanen et al,¹¹ and expands on the argument of Hubbard and Berkoff cited earlier.⁶ Partanen's et al argument is summarized here. EPSs are derived from intrafusal chain and bag fibers. MEPPs can also be recorded from spindle intrafusal fibers (Figure 2-11). The two types of activity, MEPPs and EPS, are usually seen together near the NMJ. MEPPs have been recorded at the NMJ and close to motor nerve terminals. EPS can be recorded both inside and outside the endplate zone. The electrical activity of active TrPs defined as endplate noise is identical with the EPS of muscle spindles. Fusimotor afferent (sensory) fibers include type IA and II muscle afferent mechanoreceptors that respond to muscle length change and rate of change. Group III and IV afferents are both mechano- and chemoresponders, and respond to acidosis and to algogenic substances such as kinins, 5-hydroxytryptamine, and prostaglandins. Group IA and II fibers respond to changes in muscle length, whereas group III and IV afferents respond to the chemical changes of muscle damage. Activated nuclear bag fibers have nonpropagating local activity in the area of the motor endplate. The efferent activation of the spindle is selective, occurring either at the equatorial region of the spindle or at the polar regions of the spindle. Nuclear bag fibers have junction potentials that do not propagate from the endplate region of the muscle and thus remain local. Nuclear chain fibers have propagated APs that are

confined to the polar regions of the spindle, not spreading to the equatorial region where IA afferent fibers are located. The innervation of the spindle, therefore, is selective, confined either to the polar region of the spindle or to the equatorial region. A single axon will generally innervate just one spindle pole. Spindle electrical activity, therefore, is highly localized. However, in contrast to the spindle theory, two-thirds of the EPS discharges have a negative onset, consistent with an endplate origin, but not spindle origin. Moreover, spontaneous fusimotor activity does not occur in the relaxed muscle, at a time when SEA is present. Partanen et al further observe that group III and IV afferent activity increases with persistent muscle contraction and fatigue, whereas the firing rate of alpha motor units decreases.¹¹ Alpha motor neuron activity is inhibited, whereas gamma efferent activity is increased. Because gamma and beta efferent nerves innervate more than one spindle, there is some local spread of activity possible. Persistent muscle overload may result in neurogenic inflammation and sensitization of group III and IV afferents, making them more vulnerable to work overload. Partanen et al¹¹ postulated that muscle overload leads to the development of an “inflammatory soup” of algescic substances, similar to that proposed by Simons in his Integrated Hypothesis,¹ that sensitizes the group III and IV afferent sensory nerves, leading to a reflex activation of gamma and beta efferent drive. He postulates that beta efferent activation causes fatigue, energy crisis, and then silent contracture of the extrafusal fibers of the beta units, which are then palpable as taut bands. CRDs occur transiently in the developing taut band that finally fatigues and becomes a silent contracture (rigor). The aberrant activity may spread to neighboring, less active spindles, activating their beta motor units, leading to expansion of the taut band. The local twitch response is postulated to arise from the stimulation of IA afferent fibers, giving rise to a reflex arc involving intrafusal group III and IV afferents and beta efferent fibers.

Figure 2-11. Alpha motor neurons, gamma motor neurons, and the muscle fibers they innervate.

The depressant effect of phentolamine on the characteristic electrical activity at the TrP must be considered when evaluating the role of the muscle spindle in TrP formation. SNS stimulation of muscle spindle afferents depresses IA and II afferent-fiber activity.³⁶ Sympathetic fibers innervate intrafusal fibers, and can depress the feedback control of muscle length by inhibiting the afferent output of muscle spindle group IA and II fibers. Additionally, sympathetic activation reduces spindle responses to changes in muscle length in rabbit jaw elevator muscle, independent of gamma activity and intrafusal muscle tone, and unaffected by muscle hypoxia. Resting spindle activity is variable, decreased in IA and either increased or decreased rather equally in group II fibers. The SNS acts on the spindle at the extrajunctional regions of intrafusal fibers, at the sensory endings of group IA and

group II afferents, and at the encoder site, but not at gamma fibers.^{36,37} An alpha-adrenergic blocking agent should not depress EPS activity in the resting muscle if it arose from muscle spindles.

The muscle spindle hypothesis of TrP formation has been critiqued explicitly by Simons et al.¹ The electrical activity characteristic of the TrP is consistent with studies that localize the electrically active loci to the endplate region. The electrically active loci are chiefly found in the TrP region, somewhat in the endplate zone but not specifically at TrPs, and not found outside the endplate region. The low-amplitude endplate noise that looks like greater frequency and higher-amplitude MEPPs is highly localized to the TrP region, found only within a 1 to 2 mm wide locus. Muscle spindles are distributed more extensively in muscle than just in endplate zones, and outside the region where endplate noise is found. The morphology of TrP electrical activity is the same as endplate waveform morphology. EPSs are also found at the TrP zone, but they can be seen propagated up to 2.6 cm from the TrP along the taut band. Spindle intrafusal fibers are not that long, so that the spike activity must be propagated by extrafusal fibers. The EMG needle would not be able to penetrate the spindle capsule to record intrafusal fiber activity.

The problem has not been studied adequately pharmacologically. The systemic administration of curare should block cholinergic activity at the motor endplate and gamma activity, but not the adrenergic activity of group IA and group II afferent spindle fibers. This has not been adequately studied in TrPs, and no information regarding the selective effect of curare-like drugs on cholinergic activity in TrPs is available.

6.2. The Sympathetic Nervous System in Myofascial Pain

Implications of the Effect of Phentolamine on Endplate Noise

No currently published hypothesis adequately explains the observed depressant effect of phentolamine on the electrical activity at the TrP. Sympathetic nerve stimulation suppresses group IA activity and produces a mixed response among group II fibers. However, spindle responses to sympathetic nerve stimulation vary from one muscle to another, and among species. Nevertheless, on the basis of these studies, one would expect that blocking or decreasing SNS would increase both muscle spindle and motor endplate activity, not inhibit it. Moreover, the studies of SNS modulation of both muscle spindle activity and of motor endplate activity are done either by SNS stimulation or by examining the effects of beta-adrenergic blockade. The effect of alpha-adrenergic inhibitors has been little studied. However, there is one study of the effect of the alpha-adrenergic blocking agent clonidine that shows markedly suppressed EPPs and MEPPs, but no suppression of the quantal release of motor nerve terminal ACh.³⁸ The mechanism was thought to be a noncompetitive blockade of AChR, but not via an alpha-2-adrenoreceptor pathway on the motor nerve terminal. A possible postsynaptic effect of phentolamine on TrP formation will be discussed in the section on the role of K_{ATP} channels in muscle contraction later in this section.

Sympathetic Nervous System Effects on Calcium Flux

The alpha-1&2-adrenergic blocking agent phentolamine significantly depresses endplate noise, indicating that the electrical activity generated at the TrP zone is driven in part by the SNS.³⁹ The mechanism remains unproven. The mean average integrated signal (AIS) of TrP SEA was reported to be of 9.89 μV compared with 7.92 μV in the phentolamine group ($P < 0.05$), a significant decrease. However, the depression of electrical activity at the TrP represents a presynaptic site of action where ACh is released, especially because most postsynaptic sympathetic modulation is via beta-adrenergic pathways. One potential target of sympathetic modulation is the regulation of calcium concentration within the muscle fiber, which may be related to the maintenance of the taut band. Muscle contraction requires an increase in $[\text{Ca}^{2+}]_c$. The force of muscle contraction is directly related to $[\text{Ca}^{2+}]_c$. Mechanisms that affect muscle cell $[\text{Ca}^{2+}]_c$ can be summarized as those mechanisms that are mediated primarily by the RyR1-SR system or mechanisms mediated through other systems such as those involving second messenger systems. Ca^{2+} is also released from mitochondria. Dysfunctional mitochondria will release more Ca^{2+} than normal mitochondria, for example. Furthermore, Ca^{2+} itself induces the release of Ca^{2+} from the SR via RyR1 channels, a process known as Ca^{2+} -induced Ca^{2+} release.⁴⁰

Beta-Adrenergic Effects on Ca^{2+} Levels

Thus, there may be two broad categories of effects of the SNS on muscle contraction: (1) regulation of the excitation phase of ECC through the modulation of the AP, most likely by controlling the effective concentration of ACh at the NMJ. This has been discussed earlier. (2) Modulation of $[\text{Ca}^{2+}]_c$. There is good evidence that the SNS modulates $[\text{Ca}^{2+}]_c$. The force of contraction can be enhanced in the skeletal muscle by beta-adrenergic agonists.⁴¹ Ca^{2+} levels are modulated through beta-adrenergic effects on second messenger systems. One such pathway is mediated through cyclic adenosine monophosphate (cAMP). Beta-adrenergic stimulation increases cAMP levels, leading to increased basal levels of $[\text{Ca}^{2+}]_c$ and decreased concentration of Ca^{2+} in the SR ($[\text{Ca}^{2+}]_{\text{sr}}$) during contraction, and increased fiber contraction and efficacy of the Ca^{2+} release/uptake cycle during motor nerve stimulation.⁴² Under normal conditions, Ca^{2+} is released from the SR as described earlier, reducing $[\text{Ca}^{2+}]_{\text{sr}}$ after tetanic stimulation and even after a single stimulus-evoked fast twitch.⁴² The mechanism involves PKA-dependent phosphorylation of DHPR and possibly RyR1 as well. Beta-adrenergic stimulation increases cAMP levels and improves Ca^{2+} uptake in the SR after contraction. Complete SERCA inhibition allows muscle to contract only a few times but with greater contraction intensity, whereas resting $[\text{Ca}^{2+}]_{\text{sr}}$ is lower than in controls.⁴² $[\text{Ca}^{2+}]_c$ increase in the presence of SERCA inhibitors may be due to a reduced SR uptake of Ca^{2+} after contraction, or that a constant influx of Ca^{2+} into the cytosol from the SR that is normally masked by SERCA activity, but that it is unmasked when SERCA is inhibited. In the case of myofascial TrPs, there may be a partial inhibition of SERCA by an “energy crisis” as postulated by Simons, because of a lack of ATP, or there could be a

higher “leak” or influx of Ca^{2+} into the cytosol by leaky RyR1 or from “sick” mitochondria.

Second Messenger System Regulation of $[\text{Ca}^{2+}]_c$

Another mechanism for the increase in $[\text{Ca}^{2+}]_c$ upon beta-adrenergic stimulation may be PKA activation of glycogen metabolism, providing more glucose and therefore more ATP to explain higher Ca^{2+} loading of the SR. Both release from and uptake into the SR of Ca^{2+} are amplified in the mouse anterior tibialis muscle under beta-adrenergic stimulation.^{42, 43} Beta-adrenergic agonists augment peak contraction force (positive inotropic effect) and shorten the relaxation of slow-twitch muscles (positive lusitropic effect), except that under some circumstances a peak force reduction is induced in slow-twitch muscles.

Summary of Beta-Adrenergic Effects

Beta-adrenergic stimulation activates beta 2 adrenoceptors that are coupled to G proteins, thereby activating adenylate cyclase that converts ATP to adenosine 3', 5' cAMP. Cyclic AMP-dependent protein kinases phosphorylate certain target proteins, including DHPR, thereby altering receptor activity and ion flux.⁴³ They modulate sarcolemmal processes by increasing the resting membrane potential and increasing the action potential amplitude via enhanced Na^+ - K^+ pump and Na^+ - K^+ - 2Cl^- cotransporter function. Myofibril Ca^{2+} sensitivity and maximum Ca^{2+} -activated force are unchanged. Increase in contractile force is mediated through the phosphorylation of SR-RyR1 channels, which sensitize the Ca^{2+} -induced Ca^{2+} release mechanism. Greater Ca^{2+} loading may then contribute to force potentiation seen in fast-twitch muscles. However, some studies in humans show no force potentiation, which seems to be related to the low beta-adrenergic concentration used. High-dose beta-adrenergic agonists, however, enhance $[\text{Ca}^{2+}]_{sr}$ release rates and increase maximum voluntary strength in humans.⁴³ Beta-adrenergic effects on peak force and on relaxation do not involve myofilament processes, in contrast to cardiac muscle. Ca^{2+} sensitivity and Ca^{2+} -activated maximum force reflecting maximum cross-bridging activity are unchanged in the skeletal muscle. The positive inotropic effect is fully accounted for by ECC processes. Cairns and Borroni state that the beta-adrenergic effects on Ca^{2+} processing involve the following proteins: voltage-gated L-type $\text{CaV}1.1$ channel, the DHPR in the T-tubule membrane, phospholamban (PLB), a protein in slow-twitch fibers associated with SERCA, and RyR1.⁴³ PLB does not mediate the beta-adrenergic potentiation of force in the skeletal muscle, but it is involved in shortening the relaxation time in the slow-twitch muscle by a PKA-phosphorylation-related increase in SR Ca^{2+} uptake. The force of contraction in a given muscle, enhanced or decreased, may ultimately depend on the relative rates of Ca^{2+} release and uptake from and to the SR in that muscle, and that force will be affected by alpha-adrenergic presynaptic activity and beta-adrenergic postsynaptic activity.

Alpha-Adrenergic Effects on Muscle Function and $[\text{Ca}^{2+}]_c$

SEA endplate noise that looks like increased amplitude MEPPs and higher-amplitude EPS is decreased by the mixed alpha 1- and 2-antagonist phentolamine. MEPPs were discovered in 1950 by Bernard Katz.⁴⁴ They were first recorded intracellularly. MEPP is highly localized to the endplate region. Its activity is greatly attenuated even millimeters from the endplate region.⁴⁵ The fact that it could be recorded by extracellular electrodes led Simons to think that it was an amplified MEPP activity that was part of the endplate activity. Catecholamine activity is mediated through the presynaptic alpha-adrenergic receptors and the postsynaptic beta-adrenergic receptors.⁴⁶ Epinephrine and norepinephrine each can increase the size of MEPPs by modulating the release of ACh. Epinephrine acts at both pre- and postsynaptic receptors, at both alpha- and beta-adrenergic receptors. Norepinephrine, however, is active primarily at alpha 1- and alpha 2-adrenergic receptors. Isoproterenol, a beta-adrenergic agonist, does not affect MEPPs or EPPs. Catecholamine modulation of TrP endpoint noise has not been reported. However, knowledge of the origin of endplate noise could be useful in developing pharmacologic approaches to the treatment of MPS. Norepinephrine increases MEPP frequency and EPP amplitude. The inhibitory effect of phentolamine on EPS, and the lack of effect on MEPPs and EPPs by isoproterenol, indicates that the control of MEPP frequency and EPS amplitude are alpha-adrenergic-modulated functions. Furthermore, because it is the high-amplitude EPS discharges that are abolished by phentolamine, it may not be the NQR release of ACh that drives MEPP that is critical in reducing the AIS of endplate noise, but rather the loss of EPS. Control of catecholamine expression in humans through such modalities as meditation and mindfulness practices may, therefore, be a useful focus of clinical research.

7. ION CHANNEL POLYMORPHISMS AS A CAUSE OF INCREASED CYTOSOLIC Ca^{2+}

Ion Channel Control of Ca^{2+} Influx

Hong and Simons had already come to the conclusion by 1998 that endplate noise was caused by the leakage of ACh from the motor nerve terminal.⁴⁵ They hypothesized that the effect of a localized increase in ACh would cause excessive release of calcium from the SR (and from the ER and other sources of Ca^{2+}), causing localized sarcomere contraction, but also requiring more ATP to remove Ca^{2+} , thus causing a hypermetabolic state in the muscle, and, abetted by capillary constriction from muscle contraction, an energy crisis whereby excess Ca^{2+} remained in the cytosol, facilitating prolonged or chronic contractile interaction between actin and myosin. These ideas were embodied in the Integrated Trigger Point Hypothesis referred to earlier (Figure 2-10).

The Problem of Excessive Cytosolic Ca^{2+} : The Case of Malignant Hyperthermia

Any explanation for taut band formation and maintenance must include a process for increasing $[Ca^{2+}]_c$, because Ca^{2+} is required for the actin–myosin interaction described previously. Two mechanisms to consider are those that cause malignant hyperthermia on

the one hand and those that cause the stiffness of rigor mortis on the other hand. In malignant hyperthermia, the cytosol is flooded with excessive Ca^{2+} that overwhelms the processes that remove it from the cytosol.⁴⁷ The problem of excessive cytosolic Ca^{2+} in malignant hyperthermia is that a mutation in an RyR1 subunit allows it to stay open longer than it normally does, allowing more Ca^{2+} to leave the SR and enter the cytosol. There are over 100 known mutations of this receptor. Gain of function mutations causes the ion channel to be open for prolonged periods. Thus, there is uncontrolled entry of Ca^{2+} into the cytosol where it interacts with tropinin to allow actin and myosin cross-bridging to occur.

Ca^{2+} must be removed from actin in order to reverse cross-bridge formation and allow the muscle to relax, and the sarcomere to lengthen. Reuptake of Ca^{2+} into the SR is an ATP-dependent energy-requiring process. The process releases energy in the form of heat, which is why persons with malignant hyperthermia develop high fevers. In malignant hyperthermia, ATP is depleted, Ca^{2+} is not removed from the cytosol, and muscle contraction is prolonged.

Rigor Mortis: The Ultimate Depletion of ATP

A different situation occurs in rigor mortis, where there is increased permeability of cell membranes to Ca^{2+} and an accumulation of Ca^{2+} in the cytosol. ATP cannot be regenerated, so that Ca^{2+} is not removed from the cytosol. Cross-bridges remain, and the muscle is stiff. A third mechanism not involving $[\text{Ca}^{2+}]_c$ is static stiffness, discussed subsequently.

The Role of ATP

If the mechanism for taut band development involves excessive $[\text{Ca}^{2+}]_c$, then we must have a mechanism to explain this. One mechanism of increasing $[\text{Ca}^{2+}]_c$ is by increased NQR of ACh from the motor nerve terminal. That possibility has been discussed in conjunction with MEPPs, EPPs, and endplate noise. We still do not know if reduction in EPS is accompanied by reduction in hardness or stiffness of the taut band. We also do not know if the presumed increase in the NQR of ACh is sufficient to cause focal sarcomere contraction as it is hypothesized, or if it is sufficient to cause the formation of taut bands. Mense et al showed that the inhibition of AChE caused focal muscle fiber contraction, but they were distributed along the muscle fiber and were not located precisely at endpoint regions.⁵ Nevertheless, they showed focal sarcomere contractions, although they looked more like disks and differed in appearance from the hypothesized TrP contraction knots. Second, the development of the taut band may be unrelated to the NQR of ACh. It may instead be related to the relative ischemia secondary to capillary compression that excessive muscle contraction may produce, resulting in a decrease in ATP availability. Lack of sufficient ATP may affect the concentration of Ca^{2+} in a way that has not previously been considered. This will be discussed in more detail subsequently.

8. REACTIVE OXYGEN SPECIES AND MUSCLE DYSFUNCTION: JAFRI'S HYPOTHESIS

An interesting and novel hypothesis for TrP formation and maintenance has been proposed by Jafri and described in detail in his discussion on the nature of TrPs.⁴⁸ Jafri's concern is that the current theories of TrP formation do not adequately explain what we currently know about the TrP. In particular, he addresses the question of the persistent hypercontraction of the taut band. He suggests a mechanism that would sustain an elevated level of $[Ca^{2+}]_c$ to drive the process. Jafri's theory is based on the observation that increased muscle activity generates reactive oxygen species (ROS). ROS are overproduced by excessive striated muscle activity (muscle overload). Ischemia at the TrP region decreases the mitochondrial membrane potential and leads to excessive extramitochondrial proton (H^+) accumulation, thereby lowering intracellular pH, reducing the ability of the mitochondria to remove ROS. ROS are normally removed by superoxide dismutase, which converts superoxide to hydrogen peroxide (H_2O_2) and ultimately to oxygen and water through catalase or glutathione peroxidase pathways. Repetitive muscle contraction results in the generation of ROS through phospholipase A2, xanthine oxidase, or NADPH oxidase (NOX) pathways. Mechanical deformation of the T-tubule system acts as a mechanotransducer that activates NOX2, which also results in the production of ROS. Activated ROS also deform the T-tubule, increasing their density, and contributing to the hypoechoic appearance on ultrasound of the TrP. Furthermore, ROS oxidize RyRs, opening them to Ca^{2+} influx from the SR. The sarcolemma "transient receptor potential" channels become sensitized; these are essential for maintaining the integrity of the SR during repetitive muscle contractions. The ROS signaling cascade in the skeletal muscle just described is maladaptive, because it maintains excessively high levels of $[Ca^{2+}]_c$. The great excess of $[Ca^{2+}]_c$ in TrPs is thought to lead to focal muscle contraction and regions of increased sarcomere lengthening, or muscle stretch, further activating ROS. The result is a persistent increase in $[Ca^{2+}]_c$ and muscle fiber contraction. This mechanism, Jafri proposes, acting through microtubule cytoskeletal elements and activation of NOX, produces ROS, causes excessive Ca^{2+} to enter the cytosol through RyRs, and causes local sarcomere contraction.

Jafri's hypothesis addresses the issue of energy depletion or a decreased concentration of ATP generated by mitochondria, proposed in the Integrated Hypothesis of the TrP as the increase in ROS concentrations is associated with mitochondrial dysfunction.^{1,22} It addresses the development of the TrP from muscle overuse and also the muscle weakness associated with the TrP. It does not address the role of the SNS in the formation of the taut band but neither does it exclude a role of the SNS. Jafri's model offers a credible explanation for the development and maintenance of the TrP taut band that is compatible with other possible mechanisms, and that fills in some of the details of Simons' Integrated Theory.

9. A NEW HYPOTHESIS: K_{ATP} RECEPTOR CHANNEL

POLYMORPHISMS

9.1. K_{ATP} Activation and Trigger Points: A New Construct

The key to the answer of how the taut band is formed and maintained may be found in the K_{ATP} channel. The K_{ATP} channel is a potassium channel that is ATP sensitive. The K_{ATP} channel is kept closed when ATP is at physiologic levels. An open or active K_{ATP} channel inhibits Ca^{2+} influx into the cytosol from the SR and the ER. A fall in ATP levels, as occurs in hypoxia or ischemia, opens the K_{ATP} channels. Open K_{ATP} channels lead to membrane hyperpolarization, shortening of the AP, and inhibition of voltage-gated Ca^{2+} channels. Ca^{2+} influx into the cytosol is decreased, particularly that from the SR. Reducing $[Ca^{2+}]_c$ minimizes the risk of Ca^{2+} overload and also reduces the likelihood of developing excessive ROS. Protons (H^+) also open K_{ATP} channels. Phentolamine, shown to decrease the EPS as described earlier, has the additional effect of blocking ATP release, thereby lowering ATP levels, which can lead to K_{ATP} activation. Hence, the action of phentolamine on TrPs may be both presynaptic at α_1 -adrenergic receptors, and postsynaptic, activating K_{ATP} channels. In cardiac muscle, phentolamine also reduced the frequency and amplitude of pacemaker currents.⁴⁹ The relevance of this modulation of cardiac currents on TrPs has not been examined.

K_{ATP} channels are energy sensors in that they respond to ATP levels. Boudreault et al link the energy state of the muscle fiber to the electrical activity of the cell membrane, regulating K^+ ion efflux.⁵⁰ Activation of K_{ATP} channels results in lower-amplitude action potentials, which may be reflected in the effect of phentolamine on EPS that in turn reduce Ca^{2+} release from the SR, and thereby decrease force generation. Activation of K_{ATP} channels results in faster onset of fatigue.

K_{ATP} Channel Deficiency

K_{ATP} -deficient mice develop supercontracted single muscle fibers, greater increases in unstimulated (not the result of a nerve stimulus) $[Ca^{2+}]_c$, greater unstimulated force, and lower force recovery.⁵¹ Impaired K_{ATP} function alters muscle response during fatiguing exercise. Downregulation of K_{ATP} activity in the fast-twitch muscle is associated with weakness.⁵² Contractility is dysfunctional, actin–myosin cross-bridge formation is depressed, and force generation is impaired.

K_{ATP} Polymorphisms

There are four K_{ATP} subunits, SUR-1, 2A, 2B, and Kir6.2.⁵³ Subunit mutations can occur that can lead to a loss of function and loss of the regulation of $[Ca^{2+}]_c$ at the time of intensive or repetitive exercise, thereby resulting in muscle fiber damage and in the development of prolonged actin–myosin interaction, leading to prolonged muscle

contractility. Lack of functional K_{ATP} channels results in impaired energy metabolism in muscle fatigue such that CO_2 generation is decreased and lactate production is increased, despite an increase in the production of ATP to try to meet the energy demands associated with muscle fatigue.⁵⁴ Muscle fiber damage can lead to the cascade of events that lead to nociception and pain.

9.2. Implications of Polymorphisms and Channelopathies: A New TrP Construct

The current model of TrP formation is that acute or chronic muscle overload initiates a chain of events, resulting in the development of the taut band and of pain. The mechanism of injury that initiates the cascade of events is not known, but is thought to be focal muscle fiber damage, ischemia, and hypoxia. One possible mechanism is that excessive or intensive muscle activity reduces intracellular ATP, resulting in the activation of K_{ATP} channels. This reduces the amount of Ca^{2+} released from the SR as well as decreasing the reuptake of Ca^{2+} into the SR. This results in lower action potential amplitude, decreasing the force of contraction that can be generated, and ultimately leading to muscle damage that can occur in ischemia-reperfusion-induced apoptosis that K_{ATP} channel activation ordinarily modulates.⁵⁵ Moreover, if the K_{ATP} channel is not fully functional, focal supercontracted regions occur in single muscle fibers, suggesting that the long-considered role of excessive local concentration of ACh at the motor endpoint is not the sole or necessarily the primary cause of hyperintense sarcomere contraction. Clinically, we find that some persons with acute muscle overload recover well, and others do not. It could be that mutations in the RyR1 Ca^{2+} channel or in the genes coding the subunits for the K_{ATP} channel result in or contribute to the features of the TrP, or contribute to them.

10. STATIC STIFFNESS

10.1. Static Stiffness: An Additional Muscle Stiffening Mechanism

The first mechanical change that occurs with muscle contraction is an increase in stiffness before contraction, when there is zero active force.⁵⁶ Cross-bridging is one means that brings this about and is Ca^{2+} dependent. Some stiffness is not related to cross-bridging. Stiffness increases throughout the whole rise in tension during a muscle twitch because of the formation of cross-bridges between actin and myosin in the overlap region of the sarcomere. Static stiffness occurs in response to muscle fiber stretching. An increase in calcium-dependent static tension occurs before cross-bridging can take place. Static stiffness is dependent on sarcomere length and is independent of stretching amplitude and stretching velocity. Stiffening first occurs during the latent period between muscle fiber stimulation and active cross-bridging between actin and myosin molecules. The peak occurs shortly after activation. It is related to the length of the sarcomere, increasing as sarcomere length increases, peaking, but then decreasing as sarcomere length is further increased, exceeding the length at which actin and myosin no longer overlap.⁵⁷

Titin

Titin is the most likely candidate for the component of the sarcomere that contributes to passive stiffness. Titin regulates passive force in the myofibril and stabilizes the ordered arrangement of myofilaments in the latent and early phases of contraction.⁵⁶ Titin spans half of the sarcomere and is anchored to the Z-line and to the M-line (Figure 2-12). Titin helps to center myosin in the middle of the sarcomere. The I-band portion of titin contains a highly elastic PEVK segment that changes conformation and shortens when combined with Ca^{2+} .⁵⁸ Titin attaches to the thin actin filament, so that the shortened flexible region of titin + Ca^{2+} effectively shortens, stiffening the thin filament.^{57,59} Nocella et al comment, however, that PEVK segments stiffen without change in length and therefore without effect on force and therefore would not necessarily cause fiber stiffening.^{57,58} Slow muscle fibers like those in the soleus muscle have larger titin isoforms, and their stress–strain relation is shifted to longer sarcomere length.^{57,60} Static stiffness is greater and develops faster in fast muscle such as the extensor digitorum longus muscle.⁵⁸ There are no studies looking at differences between taut bands in slow and in fast muscle in human subjects or in animal models.

Summary of Static Stiffness

We have concentrated on the concept of intense sarcomere contracture as the heart of the TrP in recent years, considering that to be the underlying morphologic change in muscle. However, the sarcomeres on either side of the so-called contracture knots are stretched. The work from the lab of Bagni et al and others suggests that there may be increased static stiffness in the elongated sarcomeres, and that static stiffness may contribute to the persistent muscle contraction that we see in the taut band.^{58,59} Moreover, static stiffness increases up to a point with stretching of the sarcomere, but stretch beyond the overlap region of actin and myosin reduces static stiffness. This may explain why stretching exercises as used therapeutically in the treatment of TrPs may reduce the degree of hardness in the taut band as well as tenderness.

Figure 2-12. Sarcomere.

11. CONCLUSION

All credible theories of TrP formation address the issue of excessive muscle activity and of persistent muscle contraction. Some hypotheses, like Jafri's, address one particular part of the puzzle, the development of the contracted, taut band, whereas others are more comprehensive, or combine several aspects, such as the role of the alpha-adrenergic and beta-adrenergic SNS activity and aspects of control of $[Ca^{2+}]_c$. It is likely that the dysfunction caused by excessive muscle activity is multifaceted, and involves multiple pathways, including possible RyR1 mutations, K_{ATP} channel mutations, SNS regulation of both presynaptic ACh release and of postsynaptic Ca^{2+} flux, of ROS overproduction, stiffness produced by altered titin function, and an increase in NQR ACh caused by lowered concentrations of ATP. Thus, we are presented with a fruitful field for investigation to try to better characterize the processes that lead to the TrP taut band. Research needs to be undertaken to evaluate the response of the TrP SEA to various catecholamine agonists and antagonists to better understand the role of the SNS in TrPs, to explore the fatigability and recovery times of muscles with TrPs to better understand the role of ROS and of K_{ATP} in TrP muscle function, to see if substances like caffeine affect the TrP, giving information about RyR1 function, and to see if passive stretch affects SEA, to explore the role of the muscle spindle. Studies of the muscle histology of animals with trigger zones could expand our knowledge of the morphology of the TrP and allow further exploration of pharmacologic manipulation of the TrP to be studied. There is much yet to be done in TrP research. It is hoped that this discussion has opened new areas to consider in this very common condition.

The Role of Muscles and Fascia in Myofascial Pain Syndrome

Jan Dommerholt

1. INTRODUCTION

Travell and Simons defined myofascial pain syndrome (MPS) as “the sensory, motor, and autonomic symptoms caused by myofascial trigger points,” with the additional comment that a clinician would need to identify the specific muscle or muscle group that causes the problem.¹ They defined a myofascial trigger point (TrP) from a clinical and an etiological perspective. According to the clinical definition, a TrP is “a hyperirritable spot in skeletal muscle that is associated with a hypersensitive palpable nodule in a taut band. The spot is painful on compression and can give rise to characteristic referred pain, (or other symptoms) referred tenderness, motor dysfunction, and autonomic phenomena.” The etiologic definition of a TrP is “a cluster of electrically active loci each of which is associated with a contraction knot and a dysfunctional motor endplate in skeletal muscle.” In an overview chapter in the previous edition of this book, the authors devoted several pages to the anatomy, structure, and function of muscles with detailed descriptions of the neuromuscular junction, motor unit, and motor endplate zone.¹ Although Travell opted to use the term “myofascial,” the previous editions of the Trigger Point Manual contain practically no information about fascia or about the interactions between muscle and fascia. In fact, the indices of the two-volume book did not include an entry of the word “fascia,” other than in the context of “trigger points in fascia.”²

Nevertheless, muscles and fascia are strongly related to each other and it is not really possible to discuss MPS and TrPs without considering what role fascia may play in their etiology and in the symptoms commonly attributed to muscles and TrPs. The contributions of fascia are undervalued. Although Travell was probably one of the early physicians to recognize the importance of fascia in myofascial pain conditions, the knowledge about fascia was in its infancy when she defined the terms. This chapter aims to provide a review of the anatomy and functions of muscles and fascia in the context of myofascial pain. In the current thinking, only muscular TrPs are recognized, whereas

Travell and Simons also considered cutaneous, ligamentous, periosteal, and nonmuscular TrPs.¹

2. MUSCLES

Skeletal muscles represent approximately 42% to 47% of the human body mass. They are crucial for human movement, balance, breathing, eating (activities of daily living), regulating homeostasis and metabolism, and in the widest sense, for survival.³ Most muscles attach to bones via their tendons, but some muscles attach to another muscle's tendon, such as the flexor accessorius muscle, which attaches to the tendons of the flexor digitorum longus muscle. In a few cases, muscles attach to another muscle(s), such as the zygomaticus muscles, the risorius, and the buccinator muscles attaching to the orbicularis oris muscle. Muscles actively generate forces when they contract and passively, they can be lengthened and stretched.

Muscles can be classified on the basis of their predominant type of fibers. Type I fibers are slow oxidative fibers with a slow contraction speed and a low myosin ATPase activity. They are designed for aerobic metabolism. Type IIa fibers are fast oxidative-glycolytic fibers and have a fast contraction speed and a high myosin ATPase activity. Typically, they are recruited when additional activity is required. Type I and IIa fibers are resistant to fatigue and are rich in mitochondria and myoglobin. Type IIb fibers are fast glycolytic fibers with a fast contraction speed and a high myosin ATPase activity. They are easily fatigued and have few mitochondria and little myoglobin. They generate adenosine triphosphate (ATP) by the anaerobic fermentation of glucose to lactic acid. Type I fibers correspond to the “dark meat” muscles of a chicken and mostly involved with posture and endurance sports, whereas type IIb fibers are found in “white meat” muscles and are better suited for short-term muscle contraction.

2.1. Muscle Anatomy and Physiology

Muscles are made of groups of fascicles, consisting of muscle fibers and myofibrils. A muscle fiber encloses approximately 1000 to 2000 myofibrils in most skeletal muscles. Each myofibril is approximately 1 to 2 μm in diameter and is separated from surrounding myofibrils by the mitochondria, the sarcoplasmic reticulum, and the transverse tubular systems or T-tubules (Figure 3-1). Each fibril consists of a chain of sarcomeres, which are the muscle smallest contractile elements. Muscles tend to have more sarcomeres, when the force-generating axis is parallel to the direction of the muscle fibers.⁴ When skeletal muscle fibers are activated, the length of various sarcomeres can vary substantially, and it has been suggested that this nonuniformity would contribute to mechanical instability⁵; however, when muscles are contracted isometrically, the nonuniformity has no impact on stability.⁶

Figure 3-1. Macroscopic anatomy of the skeletal muscle. Muscle fibers are organized into muscles by successive layers of connective tissue, including the epimysium, perimysium, and endomysium. This arrangement separates and protects fragile muscle fibers while directing forces toward the bone. The sarcolemma envelops the nucleus, mitochondria, and myofibrils. Myofibrils contain well-organized proteins that overlap and form Z-lines, I bands, and A bands. The sarcoplasmic reticulum houses calcium and the transverse tubules transmit electrical signals from the sarcolemma inside the cell, both critical to muscle

function.

A sarcomere has contractile and structural proteins that together form a highly organized and structured network or lattice. Individual myofilaments have more or less fixed lengths and do not change much during contractions. A sarcomere consists of thin actin filaments, which are double-stranded helical polymers attached to the Z-line, and thick myosin filaments in the center of the sarcomere. Myosin features cross-bridges with ATPase and actin-binding sites. Titin, the largest known vertebrate protein, connects the myosin filament to the Z-line (Figure 3-2). It has established cross-links with titin molecules of adjacent sarcomeres. Titin filaments generate passive tension when sarcomeres are stretched and provide muscle stiffness. It keeps the myosin filaments positioned in the center of the sarcomere.^{7, 8} A small section of titin, the PEVK segment, interacts with actin filaments close to the Z-line. It is conceivable that this connection may create a “viscous bumper” of the actin–titin interaction, comparable to a dragnet.^{9, 10} Although titin functions like a spring during stretches and eccentric loading, it turns into a sticky gel-like structure at the Z-line during concentric contractions,^{7, 8, 11, 12} which makes it possible for the muscle to generate force.¹³ Trigger points may have a damaged sarcomere assembly, with myosin filaments getting stuck in the sticky titin substance at the Z-line after breaking through the actin–titin barrier.

Figure 3-2. Sliding filament mechanism. A, Prior to transmission of the action potential, no cross-bridges connect actin and myosin. B, Once the active sites are revealed and myosin heads bind to actin, the power stroke occurs. Synchronized movement of the myosin heads pulls the ends of the sarcomere together, shortening the muscle. C, Energy from adenosine

triphosphate releases the myosin heads and positions them for another power stroke.

Another important protein is nebulin, which covers the full length of the actin filaments. Nebulin interacts with actin, titin, and the Z-line protein myopalladin.¹⁴ Titin and nebulin interact especially during myofibrillogenesis.¹⁵ Nebulin connects to the proteins desmin and myopalladin and in the Z-line. Desmin filaments connect adjacent Z-lines and interconnect the myofibrils with the sarcolemma, the nuclei, the T-tubules, the mitochondria, and possibly the microtubules.^{16,17} Myopalladin binds to alpha-actinin, which in turn connects to actin and to titin.¹⁷ Nebulin stabilizes the sarcomere through multiple binding sites at actin, tropomyosin, troponin, and tropomodulin (Figure 3-3).^{15,16,18-20} It regulates muscle contractions by inhibiting the cross-bridge formation until actin is activated by Ca^{2+} .²¹ Troponin, a Ca^{2+} receptive protein, sensitizes actomyosin to Ca^{2+} together with tropomyosin, among other functions.²² Tropomyosin and tropomodulin can influence molecular processes related to synaptic signaling and modulate neuronal morphology (Figure 3-4).²³

Figure 3-3. Sarcomere.

Figure 3-4. The molecular basis of muscle contraction. The binding of Ca^{2+} to troponin shifts tropomyosin and allows the myosin heads to bind to the actin filament. Then the myosin heads pivot, causing the filaments to slide with respect to one another.

Each muscle fiber is innervated by a single axon from an alpha-motor neuron in the spinal cord. An alpha-motor neuron with all the muscles fibers it innervates is referred to as a motor unit. There are considerable size differences between alpha-motor neurons and differences in excitability. Smaller motor neurons are more excitable than larger neurons. Similarly, smaller motor units feature a smaller alpha-motor neuron cell body, smaller axons, and fewer target muscle fibers than larger motor units (Figure 3-5). They supply in between 300 and 1500 muscle fibers and are involved in maintaining posture and activities such as walking (type I fibers), whereas larger motor units are activated with activities that require faster responses (type IIb fibers).

Figure 3-5. The structure of the skeletal muscle. A, Each muscle fiber is innervated by a single axon. B, A motor unit and motor neuron pool. (a), A motor unit is an alpha-motor neuron and all the muscle fibers it innervates. (b), A motor neuron pool is all the alpha-motor neurons that innervate one muscle.

When the cell body of a motor neuron in the anterior horn initiates an action potential, the potential propagates along the axon through each of its arborizations to the specialized nerve terminal that helps form the neuromuscular junction (motor endplate) on each muscle fiber. On arrival at the nerve terminal, the electrical action potential is relayed chemically across the synaptic cleft of the neuromuscular junction to the postjunctional membrane of the muscle fiber (Figure 3-6). T-tubules, located perpendicular to the long axis of the muscle fiber with two zones of transverse tubules to each sarcomere, conduct impulses from the exterior to the interior of the muscle fiber and activate voltage-dependent L-type calcium channels in the transverse tubular membrane, including surface membrane calcium channel dihydropyridine receptors and type 1 sarcoplasmic reticulum calcium release ryanodine receptors. Activation of these channels and receptors results in the release of Ca^{2+} into the myoplasm.²⁴ Muscle contractions occur after actin and troponin are activated by Ca^{2+} , which is stored in the sarcoplasmic reticulum. Calcium facilitates tropomyosin to shift its position and expose myosin-binding sites on actin, thus regulating the cross-bridge interactions between actin and myosin.¹⁶ Both calcium and ATP are critical for the maintenance of the actin–myosin cross-bridges.²⁵

Figure 3-6. Neuromuscular junction. A, Neurons and muscle fibers communicate at the neuromuscular junction. B, Electrical signals travel along the axon and stimulate synaptic vesicles at its end to release acetylcholine, a neurotransmitter, into the synaptic cleft. C, Acetylcholine crosses the synaptic cleft and binds to receptors in the sarcolemma of muscle fibers, causing changes within the muscle cell that initiate muscle contraction.

Henneman demonstrated that in response to increasing physiologic excitation, motor neurons are recruited in order of increasing size,²⁶ which later became known as Henneman's size principle.^{27–29} Henneman's size principle demonstrated that small motor units innervating type I slow oxidative fibers are recruited first, followed by type IIa fast oxidative fibers, and eventually by type IIb fast glycolytic fibers. Hägg incorporated Henneman's size principle into the Cinderella Hypothesis and postulated that continuous activity of smaller motor units in sustained contractions may result in muscle fiber damage, especially to type I fibers.^{30–32} It is indeed conceivable that in sustained low-level contractions and in dynamic repetitive contractions, ischemia, hypoxia, and insufficient

ATP synthesis in type I motor unit fibers are responsible for increasing acidity, an accumulation of Ca^{2+} , and subsequently sarcomere contractures with a decrease of the intramuscular perfusion, ischemia, and hypoxia.^{33–35} Several studies have confirmed the Cinderella Hypothesis,^{36–40} and it is likely to be one of the possible mechanisms leading to the formation of TrPs.^{34, 35}

Muscle Contractions

The main action of muscles is contraction. During concentric contractions, muscles shorten in length, whereas they lengthen during eccentric contractions. Gerwin et al speculated that muscle overuse can lead to the development of TrPs following sustained low-level contractions, maximal or submaximal concentric contractions, and eccentric contractions.⁴¹ With dynamic and rhythmic contractions, the contraction–relaxation rhythm enhances the intramuscular blood flow, a phenomenon known as the muscular pump. During sustained muscle contractions, however, muscle metabolism is highly dependent upon oxygen and glucose, which will be quickly depleted. Sustained contractions can impair the capillary blood flow and cause ischemia, which can happen even when a muscle contracts at only 10% to 25% of its capacity. Ischemia and hypoxia have been found near TrPs. Brückle et al documented low-oxygen saturation levels in patients with low back pain,⁴² and researchers at the US National Institutes of Health and George Mason University documented a retrograde blood flow in the vicinity of active TrPs, characterized by increased systolic velocities and flow reversal with negative diastolic velocities.⁴³ A few sessions of dry needling were able to reverse this process with objective tissue improvements up to 8 weeks after the intervention.^{44, 45} Patients with TrPs in the upper trapezius muscle experienced a reduction of pain as much as 6 weeks after dry needling.^{46, 47}

An individual muscle's maximum voluntary contraction is highly dependent upon the architecture and shape of the muscle and the development of intramuscular pressure.^{48–50} Not all muscles have the same shape and architecture, and depending on the pattern of the muscle fascicles, they are classified as parallel (eg, the rectus abdominis muscle), pennate (eg, the deltoid muscle), convergent (eg, the pectoralis major muscle), or circular (eg, the orbicularis oris muscle). Parallel muscles are by far the most common type accounting for about 85% of all muscles, and they are useful especially when speed is important. Pennate muscles are better designed to develop strength.

Muscle Contractions, Mitochondria, and the Ca^{2+} Pump

Increased pressure gradients during sustained low-level exertions may contribute to the development of pain and eventually to the formation of TrPs.⁵¹ Ischemia, or the lack of blood flow, quickly leads to hypoxia, which in turn will cause a drop in tissue pH, a release of protons, and the suspension of the production of ATP by mitochondria. Mitochondria produce ATP through the process of respiration and oxidative phosphorylation

(OXPHOS), which occurs via protein complexes of the electron transport chain (ETC).

Mitochondrial function in the skeletal muscle is quite complex. It is required for muscle homeostasis and is regulated by ATP Citrate Lyase (ACL). Citrate lyase is a cytosolic enzyme that catalyzes mitochondria-derived citrate into oxaloacetate and acetyl-coenzyme A (acetyl-CoA).^{52–54} Acetyl-CoA is oxidized to carbon dioxide and water through the tricarboxylic acid cycle, which generates reduced nicotinamide adenine dinucleotide (NADH). The ETC oxidizes reducing equivalents NADH and a reduced form of flavin adenine dinucleotide, which creates a H⁺ gradient across the mitochondrial membrane. The gradient facilitates the phosphorylation of adenosine diphosphate (ADP) to ATP by mitochondrial ATP synthase.⁴ The ATP synthesis is the most prevalent biochemical process in the human body. Active individuals produce their own body weight of ATP every day.

Exercise provides one mechanism of improving mitochondrial function, in addition to increasing the contractile function of the skeletal muscle and improving muscle strength, endurance, and aerobic capacity.⁵⁵ Muscle strengthening improves muscle functioning by increasing its metabolic capacity.

Some of these effects are mediated by insulin growth factor 1, an anabolic growth factor that induces the activation of ACL,^{52,55} and stimulates muscle hypertrophy, fatty acid uptake, and glucose metabolism.⁵⁶ Citrate Lyase also stimulates cardiolipin synthesis and mitochondrial supercomplex activity, which further improve mitochondrial function.⁵² Cardiolipin is an important component of the mitochondrial membrane.⁵⁷ The term “mitochondrial supercomplex activity” suggests that the ETC is not a static entity in the inner mitochondrial membrane, but a complex dynamic entity. There are two concurrent OXPHOS models. According to the fluid state model, OXPHOS complexes diffuse freely in the mitochondrial inner membrane, whereas the solid-state model maintains that OXPHOS complexes are organized in rigid higher-order assemblies known as supercomplexes or respirasomes.^{58,59} They consist of a combination of four complexes in the ETC that are still poorly understood.⁶⁰

As already mentioned in Chapter 2, ATP is required for the removal of Ca²⁺ from the cytosol to reverse actin–myosin coupling. When ATP is attached to the myosin molecule, the link between myosin and actin weakens, and the myosin head detaches from actin. At the same time Ca²⁺ ion detaches from the troponin molecule, which blocks tropomyosin. Under normal physiologic circumstances, large quantities of free Ca²⁺ will reenter the sarcoplasmic reticulum by a functioning sarcoplasmic/endoplasmic reticulum Ca²⁺ ATPase (SERCA) pump. When energy is depleted, sarcomeres may stay contracted, until enough ATP is again available to resolve the intracellular Ca²⁺ accumulation. High concentrations of intracellular Ca²⁺ are associated with sustained sarcomere contraction and damage of the mitochondria and the muscle, which may have a causative role in the development of muscle disorders and TrPs.^{61,62} Although SERCA abnormalities have been hypothesized to contribute to the dysregulation of intracellular Ca²⁺ homeostasis and signaling in the muscles of patients with myotonic dystrophy and hypothyroid myopathy, Guglielmi et al concluded that the SERCA function was not altered in these patient populations.⁶³

Trigger points can develop without muscle damage, but increased levels of intracellular Ca^{2+} can cause a disruption of the cell membrane, damage to the sarcoplasmic reticulum, which will trigger an even greater influx of Ca^{2+} , and a disruption of cytoskeletal proteins, including titin, desmin, and dystrophin. A dysfunctional SERCA pump was an integral component of the original energy crisis hypothesis,⁶⁴ but has not yet been demonstrated in patients with myofascial pain. Nevertheless, many patients with myalgia present with ragged red fibers and increased numbers of cytochrome-c-oxidase (COX) negative fibers, which are indicative of a dysfunction of the mitochondrial OXPHOS.⁶⁵ Ragged red fibers are also observed in MERFF syndrome (Myoclonic Epilepsy with Ragged Red Fibers), but not always,^{66,67} and in a wide variety of other disorders, such as hypothyroid myopathy, progressive external ophthalmoplegia, Leigh syndrome, adult-onset Pompe disease, and other mitochondrial myopathies.^{68–71} Aging is associated with an increase in mitochondrial abnormalities, and healthy older adults can present with ragged red and COX-negative fibers.⁷²

During sustained contractions, a muscle may switch quickly to anaerobic glycolysis in an effort to guarantee an adequate supply of ATP. Glycolysis involves splitting a glucose molecule into two pyruvic molecules, a process associated with the release of just enough energy to form two ATP molecules. Under aerobic circumstances, the reaction between oxygen and pyruvic acid can produce as many as 16 ATP molecules per pyruvic acid molecule, carbon dioxide, and water. Under anaerobic circumstances, however, the majority of glycolytic pyruvic acid is converted into lactic acid, which will further lower the intramuscular pH. When the capillary circulation is restricted, as in sustained low-level contractions, lactic acid may not diffuse out of the muscle as normally happens after exertions.³³

Muscle Contractions and ATP

Submaximal and maximal concentric contractions require much ATP, which initially is released from internal storage units in the muscle. After 4 to 6 seconds, the muscle will need to rely on direct phosphorylation of ADP by creatine phosphate (CP). Phosphorylation produces ATP by coupling a phosphate group to an ADP molecule catalyzed by the enzyme creatine kinase. Stored ATP and CP provide enough energy for maximum muscle power for approximately 14 to 16 seconds. Hereafter, a short period of rest is needed to replenish the exhausted reserves of intracellular ATP and CP. When ongoing ATP demands are within the capacity of the aerobic pathway, muscular activity can continue for hours in well-conditioned individuals. However, when the demands of exercise begin to exceed the ability of the muscle cells to carry out the necessary reactions quickly enough, anaerobe glycolysis will contribute more and more of the total generated ATP. Finally, the muscle will run out of ATP and sustained sarcomere contractions may occur, starting the development of TrPs.

3. FASCIA

When an athlete suffers from some kind of overload injury, it is conceivable that fascia or connective tissues, such as tendons, ligaments, and joint capsules, are loaded more beyond their capacity than muscles or bones.^{73,74} Although muscles are the main contractile tissue in the body, almost 40% of muscle force is transmitted to the fascia.⁷⁵ Each individual muscle has specific connections to the fascia,^{76–81} and there is evidence that the angle at which muscle fibers connect to the intramuscular connective tissue and the connections between the deep fascia and the epimysium contribute to the patterns of force transmission.⁸² As an example, the perimysium contributes to the lateral force transmission in the skeletal muscle.^{83–85} Perimysium has a high density of fibroblasts.⁸⁶

When muscles connect to other muscle fibers or to intramuscular connective tissue, epimuscular myofascial force transmission is directed toward connective tissues outside the muscle parameters.^{87,88} Findley reported that this mechanism does not only facilitate complicated movement patterns involving adjacent muscles, but also contributes to increased joint stability.⁸⁹ The shape of the muscle determines the angle the muscle fibers can connect to the intramuscular fascia (Figure 3-7). Awareness of the continuity of muscles and their fascial connections and their potential implications for clinical practice are important to understand along with the nature of TrPs and biomechanical considerations. At this point in time, there are only a few studies and case reports in the myofascial and dry needling literature that consider the interconnections between muscles and fascia,^{90–93} but the number of studies on fascia has grown exponentially during the past decade.^{94–105} Fascia may play a significant role in muscle contractibility and possibly in the formation of TrPs.^{106,107}

Figure 3-7. Tridimensional direction of the fascia.

3.1. Definitions

During the 2015 fourth Fascia Research Congress in Washington, DC, USA, fascia was defined anatomically as “a sheath, a sheet or any number of other dissectible aggregations of connective tissue that forms beneath the skin to attach, enclose, separate muscles and internal organs.”¹⁰⁸ This new definition was not necessarily acceptable to clinicians and researchers,¹⁰⁹ and a new committee was formed to define “the fascial system,” which in 2017, was described as follows:

“The fascial system consists of the three-dimensional continuum of soft, collagen-containing, loose and dense fibrous connective tissues that permeate the body. It incorporates elements such as adipose tissue, adventitia and neurovascular sheaths, aponeuroses, deep and superficial fasciae, epineurium, joint capsules, ligaments, membranes, meninges, myofascial expansions, periosteal, retinacula, septa, tendons, visceral fasciae, and all the intramuscular and intermuscular connective tissues including endo-/peri-/epimysium.

The fascial system interpenetrates and surrounds all organs, muscles, bones and nerve fibers, endowing the body with a functional structure, and providing an environment that enables all body systems to operate in an integrated manner.”¹⁰⁵

Muscles and fascia are intimately intertwined and connected. All muscles are enveloped by the epimysium. Individual muscle fiber bundles are situated within the perimysium and individual muscle fibers are contained within the endomysium. The endomysium, perimysium, and epimysium are components of the deep fascia,^{86,97} not to be confused with the visceral and superficial fascia.¹¹⁰ Stecco’s Functional Atlas of the Human Fascial System gives an outstanding overview of fascial connections in the human body.¹¹¹

3.2. Some Biomechanical Considerations

The importance of the interconnections between muscles and the epimysium, perimysium, and endomysium are slowly being realized. Each muscle has specific connections with the fascia,^{77,80,81,112} and these connections allow force transmissions to take place from muscles to bones and to deeper fascial layers. It is truly impossible to separate the fascia from other structures, such as the skin, ligaments, and muscles (Figure 3-8).^{82,113} Muscle fibers frequently connect to other muscles or to the connective tissue and these interconnections allow muscles to exert force on the fascia and connective tissues outside the muscle parameters.⁸⁸ A decline in flexibility and mobility with aging can be ascribed to changes in the fascia, such as decreased flexibility of the epimysium. Dense epimysium often restricts muscle function⁷⁶; for example, the perimysium can increase muscle stiffness and is sensitive to changes in mechanical tension.⁸⁵

Figure 3-8. Fascial connections to the skin, muscles, and nerve.

Changes in fascial pliability can lead to altered movement patterns, local overuse, and a loss of strength and coordination. Stecco et al speculated that decreased viscoelasticity is due to a lack of hyaluronan (HA), which determines the viscosity between the deep fascia and the muscle.^{76, 114} Hyaluronan is a glycosaminoglycan polymer of the extracellular matrix (ECM) and is found between muscle fibers, nerves, and the fascial layers.^{115, 116} Decreased mobility between the layers of the aponeurotic fascia, such as the thoracolumbar fascia, will lead to stiffness and limited mobility. The aponeurotic fascia consists of two or three layers of parallel collagen fiber bundles oriented in different directions and is directly connected to muscles and tendons.^{76, 104, 117} It transmits forces over greater distances than the epimysial fascia.¹⁰⁰ The deep fascia contains multiple mechanoreceptors,¹¹⁸ and the ability of the fascia to process mechanoreceptive input is entirely dependent upon its structural relationship with bone tissue and muscles.¹¹⁹

Fibroblasts are located within the ECM and they play a significant role in the synthesis of collagen, ground substance, elastin, and reticulin. As a side note, the ECM consists of collagen, elastic fibers, proteoglycans, laminins, matricellular proteins, and fibronectin.^{120–125} Fibroblasts register force-induced deformations in their ECM, and the mechanical stretching of fibroblasts regulates key ECM genes by stimulating the release of multiple substances, such as paracrine growth factor.⁸⁶ Fibroblasts feature integrins, which are critical for mechanical force patterning,¹²⁶ and they can register strain in response to changes in mechanical stress.¹²⁷ Under high tension, fibroblasts feature stress fibers and focal adhesions, and appear lamellar in shape, whereas under low stress, they are more or less rounded structures.^{128–130} Lamellar fibroblasts can differentiate into myofibroblasts

complete with a contractile apparatus of actin microfilaments and nonmuscle myosin.¹³¹ In other words, the fascia is not just a passive structure; it can engage in very slow contractions.¹³²

Fibroblasts are involved in wound closure, muscle contractions, and adhesions of scars.^{133, 134} Wound healing involves controlled remodeling of the ECM, which typically happens in three distinct phases (inflammation, proliferation, and remodeling). Following tissue injury, fibroblasts differentiate into myofibroblasts and deposit collagen, fibronectin, and glycosaminoglycans.¹³⁵ Fibrin and fibronectin are matrix proteins that prevent excessive blood loss. Fibronectin is relatively elastic, which makes it suitable for collagen assembly. Collagens are the major structural components of the ECM.¹²⁵ Fibrosis occurs when collagen being deposited by fibroblasts and myofibroblasts causes an increase in myofibroblasts with excessive matrix deposition and a disruption of matrix remodeling.¹³⁶

Empirically, adhesions of the scar tissue can be treated effectively with manual techniques or with dry needling by placing a needle directly into each adhesion or densification and rotating the needle unidirectionally as much as possible to the pain tolerance level of the patient.^{93, 137} When the needle releases, periodic tightening is indicated until the adhesion has been diminished or even resolved (Figure 3-9). Langevin et al have shown that the effects of acupuncture and dry needling can at least partially be explained by the mechanical stimulation of fibroblasts.^{138, 139} Rotating the needle creates a bond between the contracted fascial tissues and the needle, causing mechanical stress over fibroblasts, cytoskeletal force patterns, intracellular signaling pathways, and mechanically induced gene activation, which in turn will restore the scar's mobility and pliability, and immediately reduce the subject's hyperalgesia and allodynia.¹³⁷ The torque increases exponentially with rotating the needle, which can be objectively measured up to several centimeters from the needle location.¹⁴⁰ Persistent adhesions are likely due to dysregulation of ECM proteins. Rotating the needle inhibits Rho-dependent kinase and suppresses the induction of the tenascin-C gene. One of the best approaches to accomplish the transcription of the tenascin-C gene and to positively impact fibronectin and collagen XII is to cyclically stretch fibroblasts in the ECM. Because of the nearly immediate response, it is debatable whether adhesions found near the scar tissue are in fact examples of fibrotic tissue as is often assumed. Perhaps the adhesions reflect contractures of the fascial tissue and not fibrosis.

Figure 3-9. Filiform needle in the fascia.

3.3. Some Sensory Aspects of Fascia

To be a source of pain, fascia must contain sensory fibers and nociceptors.¹⁴¹ A rodent study showed that nociceptors were three times more common in the thoracolumbar fascia than in back muscles.¹⁴² Other studies have confirmed that lumbar dorsal horn neurons receive input not only from muscles but also from the thoracolumbar fascia.^{143–146} Because most of these neurons feature a high mechanical threshold, they are probably nociceptive neurons.¹⁴⁷ Deising et al suggested that the sensitization of fascial nociceptors following mechanical and chemical stimulation may contribute to persistent myofascial pain, especially when the fascia is being stretched, for example, as occurs during muscle contractions.¹⁴⁸ Injections of nerve growth factor, a chemical that induces severe hyperalgesia, in the fascia of the erector spinae muscles caused significant hyperalgesia, exercise-induced pain, and a decreased pressure threshold for about seven days and ongoing sensitization to mechanical and chemical stimuli for two weeks.¹⁴⁸ Injections of hypertonic saline caused more delayed onset of muscle pain when targeting the tibial anterior fascia than when injecting directly into the muscle.¹⁴⁹ Hypertonic saline injections into the fascia resulted in significantly more pain than injections in the subcutis and the muscle.¹⁵⁰ Weinkauf et al had similar findings when they injected nerve growth factor into the anterior tibialis and erector spinae muscles and their fascia.¹⁵¹ Mechanical hyperalgesia was more pronounced in the tibial fascia than in the muscle, and the thoracodorsal fascia appeared to be more sensitive than the tibial fascia.¹⁵¹ Danielson et al found peptidergic sensory nerve endings with antibodies for calcitonin gene-related peptide and substance P in the loose connective tissue of the patellar tendon.¹⁵² Of interest is also that under pathologic conditions, fascia is able to establish new nociceptive fibers that are immunoreactive to substance P.¹⁵³ The nerve endings in the fascia are located in the outer layer of the fascia, which is more or less continuous with the subcutaneous tissue. As the

middle fascial layer is primarily involved with mechanical force transmissions, it makes sense that there are no nerve endings; otherwise movement would cause pain. Tesarz et al confirmed the presence of nociceptive sP endings in the subcutaneous tissue and the outer layer of the thoracolumbar fascia, which implies again that the fascia may play a significant role in low back pain.¹⁵⁴ Ruffini, Pacini receptors, and free nerve endings have been identified in the deep fascia.^{134, 155} There is also some evidence that Pacinian receptors may be involved in high-velocity manipulation,¹⁵⁶ but there are no studies that have explored whether manual TrP therapy or dry needling specifically target Pacinian receptors. Simmonds et al hypothesized what the role of the fascia in manual therapy could entail, but they did not reach any significant conclusions.¹⁵⁷

3.4. Summary

Given the intricate connections between fascia and muscles, it is likely that the current explanatory models of myofascial pain and TrPs will continue to evolve as the knowledge and understanding increases. Schleip suggested that pain sensations from TrPs may originate from sensitized fascial nociceptors.¹⁵⁸ Treatment approaches for TrPs, scar tissue, and adhesions must involve manipulation of fascia. Manual stretching techniques will cause slow adaptations, but dry needling of the scar tissue alters the contractile elements almost immediately. The mechanisms of this phenomenon are not yet known and deserve further exploration.

Perpetuating Factors for Myofascial Pain Syndrome

Robert D. Gerwin

1. INTRODUCTION

The current concept regarding the origin of myofascial trigger points (MTrPs) states that muscle overload or excessive muscle activity, acutely or chronically, precipitates the cascade of events that leads to the development of the taut band, spot tenderness (TrP), and pain. Whether acute or chronic, repetitive or persistent, the term used to describe these conditions in this chapter is “muscle overload.” Perpetuating factors are those elements that predispose individuals to the development, or contribute to the maintenance, of myofascial pain. Perpetuating factors can be classified into those causes that are mechanical and those that are metabolic, including hormonal, nutritional, or infectious. In a broader sense, these perpetuating factors impair the ability of a muscle to respond appropriately so that the muscle becomes overloaded when attempting to perform an action. It is muscle overload that is thought to lead to the development of trigger points (TrPs) through the final common pathway of an energy crisis as proposed by Simons¹ and expanded on by others.² Mechanical stresses producing muscle overload can be further classified as postural or structural, and as static or dynamic (repetitive). Metabolic effects include hypometabolic states, hormonal effects, adverse effects of drugs, infection, and nutritional insufficiency. Finally, there are neuroplastic changes in the central nervous system (CNS) that can maintain nociception and amplify the perception of pain, such as the inhibition or facilitation of descending nociceptive modulating factors and central sensitization, that are now being approached therapeutically, and therefore should be considered in people with chronic myofascial pain syndrome.

Many articles and book chapters have been written about perpetuating factors, hence this chapter will focus on those factors that have not been previously well covered or discussed.³ This chapter will focus on hormonal conditions including the gonadal hormone conditions, estrogen or testosterone deficiency, and subclinical hypothyroidism; three nutritional factors, B vitamins (briefly) and vitamin D deficiency (VDD) and magnesium deficiency; and three mechanical factors, Joint hypermobility syndrome (Ehlers-Danlos

syndrome), maladaptive movement patterns in chronic pain, and forward head posture. Furthermore, the focus is on evidence-based studies and on the physiology and biochemistry underlying the effect, appropriate for the understanding needed for the clinical management of people with myofascial pain syndrome.

2. HORMONAL FACTORS

2.1. Gonadal Hormones: Estrogen

Nociception and antinociception are sexually dimorphic, modulated differently in men and women, in both humans and in laboratory animals. Women have lower pain thresholds, lower pain tolerance, and higher pain scale ratings than men as reported in many studies, although there is some variance in the reports.⁴⁻⁶ Nevertheless, the predominant finding of epidemiologic studies worldwide show that women have more chronic pain conditions such as irritable bowel syndrome, painful bladder, migraine headache, back pain, widespread pain and fibromyalgia, abdominal pain, and musculoskeletal disorders than men. Women show a greater prevalence of pain over all body sites, and a greater prevalence of inflammatory or nociceptive pain, and of neuropathic pain.^{4,5,7} Studies in pain responses in healthy women showed greater temporal summation to nociceptive stimuli than in men. Central pain modulation (CPM), ie, the ability of descending influences to inhibit pain following a conditioning nociceptive stimulus, is less effective in women in suppressing pain than in men, in most studies.^{8,9} Likewise, imaging studies show a significant difference between men and women in the activation of brain centers concerned with pain, men showing a greater responsiveness to peripheral nociceptive stimuli than women.¹⁰ Recent research focused on neuroimmune mechanisms of pain have shown that the immune system plays a major role in nociception, particularly glial cells in the CNS, as well as mast cells, macrophages and T cells that can release proinflammatory cytokines.¹¹ Estrogen even affects glial cells by increasing proinflammatory cytokines including prostaglandins and cyclooxygenase (COX). The issue of sex differences and the role of gonadal hormones have been extensively considered in the past.¹²

The difference in pain responsiveness between women and men may in large part be due to hormonal effects on the nociceptive system. Pain tends to vary over the menstrual cycle and with the level of estrogen. In addition, the effects of gonadal hormones are different peripherally and centrally. For example, women show lower pain thresholds to most experimental pain modalities than men, the exception being ischemic pain.⁵ Estrogen affects most body organs, including the CNS. The modulatory effects of estrogen are not easily described, as they differ from organ to organ. Most studies of estrogen effects on visceral pain have shown it to be pronociceptive, whereas most studies on deep somatic pain show that estrogen is antinociceptive.⁷ Pain perception and nociceptive-input suppression vary over the reproductive cycle in women.¹³ There is, therefore, great interest in the role of estrogen as a modulator of nociception.

Estrogen and testosterone are both synthesized from cholesterol. Estrone and estradiol are derived from testosterone and androstenedione through the action of the P450

aromatase monooxygenase enzyme complex,¹⁴ primarily in the ovaries, but aromatase is also found in other tissues, and in particular for our discussion, in the brain and spinal cord. There are both positive and negative feedback loops that modulate the synthesis and release of estrogen throughout the menstrual cycle, accounting, to a great extent, for the pronociceptive and antinociceptive influences of the different phases of the estrous cycle (see Amandusson and Blomqvist¹⁴ for a review of estrogen effects on pain). The effects of estrogen associated with different phases of the estrous cycle are slow and prolonged, whereas the effects of estrogen on neuronal function can be quick in response to the rapid changes of estrogen levels in the brain and nerve tissue. Estrogen effects are both genomic, acting through transcription pathways in cell nuclei for protein synthesis, and nongenomic, acting on membrane estrogen receptors that have a rapid onset of action.

Two primary theories of pain transmission must be reviewed in order to understand the action of estrogens on pain. One is that nociceptive input travels along specific pathways made up of distinct, modality-specific neurons. The other view is that the nociceptive system is comprised of multimodal neurons that, when activated, react to other sensory stimuli. Recent investigations have shown that nociceptive pathways are not solely within the somatosensory system, but are part of a homeostatic system that monitors the body status and interacts with the autonomic system, the hypothalamic–pituitary–adrenal axis, and other neuroendocrine systems, thus modulating nociceptive input and transmission.¹⁴ Nociceptive input can be magnified or diminished by facilitatory or inhibitory influences, such as estrogens, that may in part be mediated by dorsal horn interneurons that make up about 95% of dorsal horn neurons, of which about 70% are excitatory and 30% are inhibitory. The interneurons, located primarily in lamina II where C-fibers terminate, release neuromodulating substances such as substance P and calcitonin gene-related peptide. Estrogen acting on estrogen receptors in the CNS acts as a modulating factor on nociceptive transmission. Blocking of dorsal horn inhibitory interneurons results in hyperalgesia and allodynia. Secondary- and tertiary-level neurons in the thalamus, in the anterior cingulate gyrus, and in the somatosensory cortex are likewise connected to other centers such as the amygdala, hypothalamus, and prefrontal cortex. These connections are integrative and give rise to the affective responses to pain. Thus, the nociceptive pathway is interactive and integrated with other sensory centers, and with those centers related to emotion and volition.

Nociceptive input is further modulated by descending supraspinal influences that are either facilitatory or inhibitory. The predominant descending nociceptive inhibition system is the endogenous opioid system that includes enkephalin and dynorphin as mediators. Additionally, thyroid hormones and glucocorticoids may regulate the transcription of the enkephalin gene. Estrogens also have that ability in certain regions of the brain. Hence, the action of estrogen on the nociceptive system is consistent with the concept that the nociceptive system is a homeostatic system with multimodal inputs, including gonadal hormones that help regulate and maintain basal body functions.

The role of estrogens in modulating the nociceptive system is seen in animal studies where low estrogen levels are associated with increased visceral and trigeminal neuronal

sensitivity to painful stimuli.^{14,15} Estrogen modulates opioid analgesia as well as endogenous opioid effects. Estrogen increases endogenous opioid production in both the brain and spinal cord of ovariectomized rats. Estrogen also modulates the expression and activity of opioid receptors in pain-related brain regions, affecting responses to both exogenous and endogenous opioids. The relevance of estrogen to pain in humans is suggested by studies that show that women given hormone replacement therapy (HRT) have higher levels of orofacial pain and lower pain thresholds and tolerances.¹⁶ However, the effects are complex because estrogen also affects the levels of pro- and antinociceptive substances in the dorsal horn and has varying effects on pain, with no change in pain in women with fibromyalgia syndrome (FMS) taking HRT, but reduced levels of musculoskeletal pain compared with control subjects.

The estrogen effect may be direct, acting on estrogen receptors in the nervous system, or indirect, mediated through other systems such as the endorphin system.¹³ Estradiol (17- β -estradiol) can be both pronociceptive and antinociceptive in female rats. A direct effect on transcription is mediated through nuclear estrogen receptors, through a genomic effect, and through G-protein-coupled estrogen receptors (GPER) on the plasma membrane where they activate signaling cascades of second messenger systems, affecting intracellular processes by modulating ion channel activity. These two mechanisms differ in their time courses. Activation of cell membrane GPER alters ion channel function in seconds to minutes, as opposed to genomic effects on transcription that occur over hours to days. GPER, activated by endomorphins (mu-opioid receptor ligands), may be related to the varied response in females of high analgesic responsiveness during proestrus and reduced responsiveness during diestrus. Intrathecal Endomorphin 2 (EM2) actively suppressed in diestrus in rats; spinally synthesized estrogens are required for this suppression. Suppression of spinal EM2 during diestrus results from locally synthesized estrogens activating spinal estrogen receptors that inhibit aromatase. There is a significant spinal antinociceptive response to EM2 during proestrus that is likely to be related to the loss of diestrus-associated membrane estrogen receptor suppression.¹³ Nevertheless, the mechanism by which estrogen modulates pain perception remains imperfectly understood. One study looked at the effect of estrogen on the hypothalamic–pituitary–adrenal axis as the mechanism for suppression of nociceptive responsiveness and found that antinociception was independent of COX and hypothalamic–pituitary–adrenal activity.¹⁷

Estrogen is present systemically, produced by the ovaries, but it is also synthesized in the brain, particularly in the hypothalamus, amygdala, and periaqueductal gray matter, and in the integral part of the descending nociceptive modulation system. Aromatase, the enzyme that converts testosterone and androstenedione to estrogen, is also present in the rostral ventromedial medulla (RVM) of the rat.¹⁸ The RVM is also an integral part of the descending nociceptive modulatory system and is involved both in nociceptive facilitation and inhibition. The upregulation of aromatase has been found in certain visceral pain conditions. It is now thought that the upregulation of aromatase activity in the RVM may be a factor in chronic visceral pain states.

The application of animal models to human clinical practice is fraught with

uncertainty. Human and rodent hormonal cycles differ, for example, and rodents lack the thalamocortical nociceptive-transmitting pathways present in primates that play such a prominent role in human chronic pain conditions. Moreover, the results of HRT effects on pain are mixed, with some studies showing that painful conditions are more prevalent, and other studies showing that painful musculoskeletal disorders are less common in women taking HRT. The contradictory results of studies of estrogen effects may stem from the complex nature of estrogen's relationship to body homeostatic mechanisms, so that in addition to the nature and location of nociceptive origin, the menstrual cycle stage, estrogen dosage, other drugs with which it may be given, especially progesterone, and other factors that affect body homeostasis may all play a role in the effect estrogens have on pain.¹⁴

The role of estrogen on muscle function has been studied to a limited extent. Estrogen receptor alpha mRNA is found in the human skeletal muscle, which could indicate that there is a direct action of estrogen on the muscle. The conflicting results of studies on estrogen's effect on muscle strength is not clear. One mechanism may be the regulatory effect of estrogen on the utilization of muscle glycogen used as an energy source in the muscle.¹⁹ There is a negative correlation between estrogen levels and the rate of force production and musculotendinous stiffness.²⁰ However, an earlier study from the same group showed no changes in these properties across the menstrual cycle.²¹ Male and female castrated mice had reduced maximal muscle forces, though neuromuscular transmission was intact. Muscle weight gain was diminished in female castrated mice. Thus, female gonadal hormones promote muscle activity, but the mechanisms remain unclear.²²

2.2. Gonadal Hormones: Testosterone

Testosterone also has an antinociceptive effect,²³ though it has not been as intensively studied as estradiol. The protective effect of testosterone on temporomandibular joint pain in male rats is thought to be centrally mediated through the activation of opioid receptors.²⁴ Aromatase is present in the brain and subcortical structures concerned with nociception, and can convert testosterone to estradiol. Testosterone downregulates CYP2D activity in the brain, thereby slowing the metabolism of certain opioid or opioid-related drugs centrally.²⁵ On the contrary, daily opioid use can result in androgen deficiency.^{26,27} Hence, the role of testosterone itself in pain modulation is not clear.⁴ However, gonadectomized male rats that had a drastic lowering of testosterone showed significantly more pain behavior to repetitive nociceptive stimulation than intact rats.²⁸ However, the gonadectomized rats with low testosterone had increased levels of estradiol. A pilot study of the treatment of pain in patients with FMS with testosterone reported a reduction in muscle pain, stiffness, and fatigue, and increased libido.²⁹ A study of patients with a variety of chronic, unresponsive, pain conditions (though none listed as having musculoskeletal pain) showed 32% with testosterone deficiency, including 16% of the women.³⁰ This finding is considered to be the result of the effect of chronic pain on the hypothalamic–pituitary–adrenal–gonad axis that renders it unable to meet the demands of pain-induced

stress. This deficiency is compounded by the gonadal hormone depressant effect of opioid treatment on testosterone. Treatment effect could not be ascertained from this study. However, there is a randomized controlled study in which males with opioid-induced testosterone were treated with testosterone gel for 14 weeks. The testosterone-treated group had greater improvement in pressure and mechanical hyperalgesia and body composition, in addition to greater sexual desire and improvement in role limitation due to emotional problems.³¹

There is a sexual dimorphism in the skeletal muscle in humans and in other mammals. The anabolic effect of androgens is well known. Male muscle mass is androgen dependent. Androgen receptors are present on myocytes and on muscle fiber.³² However, the effect on the muscle of male gonad-related factors that include testosterone, and that increased maximal force and improved muscle contractility, is independent of muscle growth or mass, and was found related only to male gonadal hormones and not to female gonadal hormones.²² Thus, muscle effort or maximal force is hormone dependent. It may be that the muscle that operates at a submaximal level of function is more likely to be in overload in both males and females, and therefore is more likely to develop and maintain TrPs.

The role of gonadal hormones in antinociception is complex. The effect of gonadal hormones on TrP pain is largely unknown because it has not been studied systematically, and it may be part of a general effect mediated through central nociceptive modulating pathways, perhaps in part due to the direct effect of gonadal hormones on the muscle, rather than a specific role on the TrP. The role of gonadal hormones on TrPs or on myofascial pain itself has not been studied. However, testosterone replacement in male patients with chronic myofascial pain who have low testosterone levels could be beneficial. The issue with estrogen replacement in women is more difficult to discern, but even in women who have chronic myofascial pain and where definite estrogen deficiency is established, a trial of estrogen replacement therapy may be warranted. However, if hormone replacement is undertaken, in both men and in women, a clear understanding of potential adverse effects and close monitoring of the patient are paramount. Where possible, HRT for chronic myofascial pain should be undertaken in the setting of a clinical trial.

2.3. Subclinical Hypothyroidism

Hypothyroidism has long been thought to be associated with the development and persistence of TrP pain. Dr Janet Travell often emphasized this connection in her discussions of the etiology of TrPs. She made a particular point of the effect of what we now call subclinical hypothyroidism, ie, hypothyroidism that is not overt and that is not associated with a level of the thyroid hormone (TH) that is below the limits of the range of normal. In particular, she never accepted the thyroid-stimulating hormone (TSH) level as a sufficient indicator of the metabolic state of the individual, but instead preferred to use the basal metabolic rate (BMR) test that reflected the overall metabolic state of the individual. In truth, the first generation of the TSH assay was of low sensitivity and low specificity. The BMR was a sensitive but not specific test of thyroid function, sensitive because

hypothyroidism depresses the metabolic rate, but not specific because many things alter the metabolic rate. For instance, infection and pregnancy can increase the metabolic rate and some drugs may either increase or decrease the metabolic rate. When the BMR test was no longer available, Dr Travell advocated using the basal morning temperature (taken before getting out of bed in the morning) as a surrogate for the BMR, cautioning us to beware that the use of a heating blanket could raise the basal morning temperature that would otherwise be low in subjects with hypothyroidism.³³ The current third-generation TSH assay is both sensitive and specific, except in the presence of thyroid peroxidase antibodies, which alter the correlation between free T₄ and the TSH level by the current assay method.³⁴

Both TSH and TH regulate many metabolic processes in the skeletal muscle, myogenesis and muscle fiber regeneration, and the contraction–relaxation actions of the muscle. The TSH and the TH are incorporated into muscle cells or myocytes via cell membrane and nuclear receptors that facilitate their transport across the respective membranes. Mitochondrial activity and the rate of calcium release and reuptake from the sarcoplasmic reticulum and through other means like those mediated by cyclic adenosine monophosphate (cAMP) and protein kinase A (PKA) are regulated on a rapid time basis, whereas genomic transcription affecting protein synthesis takes place over a longer time frame. Myocyte phenotype and phenotype plasticity is also regulated by the TH. Detailed reviews of the effect of the TH on skeletal muscle physiology outline these effects that are described in some further detail below.^{35,36} TSHR are present on the skeletal muscle. Therefore, the TSH may have a direct effect on the muscle distinct from that of the TH itself, and therefore may be relevant in subclinical hypothyroidism where the TSH is elevated but free TH levels are normal. TSHR mRNA and protein are found in the skeletal muscle as well as other extra thyroidal tissues.³⁷ The THS improves insulin sensitivity in mouse skeletal muscle cells, activates cAMP and secondarily PKA.³⁷ The TH itself affects muscle cell regeneration and fiber type (eg, fast or slow-twitch fibers).³⁸ The active form of the TH, T₃, is present in the muscle fiber cell, the myocyte, and helps maintain muscle homeostasis, muscle development and muscle regeneration, through binding to TH nuclear receptors. These subjects are reviewed in detail by Bloise et al³⁶ and by Salvatore et al³⁵ Three deiodinase enzymes in the myocyte regulate TH levels in the skeletal muscle. D1 removes one iodine molecule from T₄, activating the TH, D2 also converts T₄ to T₃, activating the TH, whereas D3 converts T₄ to reverse T₃, allowing for another level of control of thyroid activity. Contraction and relaxation of muscle, the result of the interaction of actin and myosin, requires calcium. Ionized calcium (Ca²⁺) levels are regulated both in the increase and the lowering of Ca²⁺ cytosolic concentrations, by TH. The expression of sarco/endoplasmic reticulum Ca²⁺ (SERCA), a group of proteins associated with adenosine triphosphate (ATP)–associated reuptake of Ca²⁺ into the sarcoplasmic reticulum, is regulated by the effect of T₃ on gene transcription. Contraction and relaxation are energy-requiring actions of the muscle that utilize glucose. Glucose utilization is likewise regulated by the TH.

The TH plays a major role in regulating muscle metabolism. Muscle constitutes about 40% of the body mass, and is a major contributor to the BMR. The genomic transcription effects of T₃, the active form of the TH, are mediated through nuclear TH receptors, similar to the manner in which TSH nuclear receptors mediate a genomic role for the TSH. The genomic effects of TSH and TH result in the upregulation and downregulation of over 600 genes in the skeletal muscle.³⁹ Moreover, T₃-regulated gene transcription plays a role in the determination of fiber type through the transcriptional stimulation of myosin isoforms. The TH also affects the contraction–relaxation cycle of the muscle, resulting in the well-known slow recovery phase of the muscle tendon reflex in hypothyroidism. The TH also stimulates mitochondrial activity and glycolysis in the muscle.^{35,36} Metabolic activity in the muscle is modulated by altering metabolic efficiency in the muscle or by uncoupling mitochondrial ATP synthesis in the muscle.

Gerwin³ reviewed the information known about the relationship of thyroid function to myofascial pain, at which time there was little clinical experience that was published, and indeed, the literature was scant on the topic.³ A major point that was made in this review, and that is still an important fact today, is that the TSH level has a rather broad range for the healthy population, but that each individual within the healthy normal range has a rather narrow range of euthyroid function. The TSH is part of the feedback mechanism that regulates the production of the TH in the thyroid gland. When the TH is insufficient, the TSH level rises, stimulating the thyroid gland to produce more TH. The importance of this relationship was evident in the treatment of a patient referred for consideration of the diagnosis of postpolio amyotrophy. Her medical records showed that 3 years prior to the referral her TSH was below 1, 2 years prior to the referral her TSH was about 2.5, 1 year before referral her TSH was about 3.5, and at the time of referral her TSH was over 4. All of the values were within the reference range for the laboratory. Because her widespread pain, and her TrP pain, subsided with thyroid supplementation treatment, the diagnosis of postpolio amyotrophy was likely erroneous.

Overt hypothyroidism clearly has an effect on an individual's level of activity, fatigue, and cardiac status, and it is recognized to be a cause of muscle cramps and pain (although the role of overt hypothyroidism in producing myofascial pain syndrome has been suspected but never actually established). Subclinical hypothyroidism is a subtler condition, but may also be symptomatic with neuromuscular manifestations relevant to our subject. Subclinical hypothyroidism occurs in up to 18% of the population in some studies, more commonly in women than in men, probably because it may occur as the result of autoimmune thyroiditis. It is defined as an elevated TSH in the face of normal free TH levels, TSH levels in the range of 4.5 to 20 mIU/L. Many subjects are said to be asymptomatic. There is a progression in some patients, particularly those with thyroid autoantibodies, to overt hypothyroidism. Subclinical hypothyroidism is not really subclinical at all in some patients, in the sense that it is not free of clinical manifestations. It is perhaps better called “mild hypothyroidism” in those patients who are symptomatic, even if the thyroid function tests are compatible with a diagnosis of subclinical hypothyroidism. In terms of muscle function, neuromuscular symptoms are common in subclinical

hypothyroidism as shown by Reuters et al⁴⁰ Cramps occurred in 54.8% compared with 25.0% in controls ($P < 0.05$), weakness in 42.2% compared with 12.6% ($P < 0.05$), myalgia in 47.6% compared with 25.0% ($P = 0.07$), and altered manual muscle testing in 30.98% compared with 8.3% ($P = 0.04$). Quadriceps strength measured by a chair dynamometer was not impaired. A more recent study of the effect of overt and subclinical hypothyroidism on the musculoskeletal system showed that there was a slight but significant elevation of creatine phosphokinase in patients with subclinical hypothyroid, as well as cramps, myalgia, and impaired physical activity (impaired 6-minute walking test), all improved with thyroid replacement.⁴¹

Studies of the treatment of subclinical hypothyroidism have shown a mild improvement in tiredness in middle-aged individuals, but no improvement compared with placebo in older individuals.⁴² However, these studies were done on large groups of subjects that included asymptomatic and mildly symptomatic subjects whose response may be quite different from the response of symptomatic patients. Treatment of subclinical hypothyroidism in the elderly with levothyroxine must be done with careful monitoring, as they are susceptible to atrial fibrillation and femoral fractures, and have a higher mortality rate than people without levothyroxine treatment.⁴³ Hypothyroidism itself, with depressed free TH levels, is associated with muscle fatigue and impaired exercise tolerance, muscle pain, cramps, and tenderness, stiffness, and loss of muscle mass. Extreme cases may present with rhabdomyolysis. The symptoms are not specific for hypothyroid myopathy, however. In hypothyroid myopathy, there is a change in muscle fiber type, with an increase in type I slow-twitch fibers and a loss of type II fast-twitch fibers, a change that may conserve energy in a hypometabolic disorder. Myofascial TrPs are not mentioned in a recent review of thyroid myopathies,⁴⁴ although hypothyroidism was present in about 10% of patients seen clinically with myofascial pain syndrome (Gerwin, unpublished data), an incidence that is not far from that found in the general population. Treatment of these patients with levothyroxine usually reduced or eliminated the myofascial pain, or noticeably facilitated the response to physical therapy treatment of TrP pain. Unfortunately, there are no adequate studies of this relationship.

Finally, insufficient levels of vitamin D (<25 ng/mL) are associated with an increased risk of autoimmune thyroiditis, and, perhaps of equal or greater significance, with elevated TSH,⁴⁵ providing another pathway to the development of muscle pain and an altered muscle fiber phenotype, with a shift away from type II fast-twitch fibers and toward slow-twitch type I fibers. This observation validates the need to consider multiple metabolic disorders coexisting in one patient. VDD, to be discussed below, is prevalent at latitudes far from the equator, but is common even close to the equator. Failure to respond to thyroid supplementation alone should raise the question of multiple metabolic disorders whether from drug usage, nutritional deficiency, parasitic infestation, or coexisting mechanical dysfunction. For this reason, a comprehensive evaluation at the outset is always recommended.

3. NUTRITIONAL FACTORS

3.1. B vitamins

B vitamins have not been shown to play a particular role in myofascial pain, although treating vitamin B₁₂ deficiency in some individuals in my practice who also had chronic widespread myofascial pain, relieved their pain. Travell, furthermore, emphasized that low vitamin B₁, thiamine, could interfere with the action of TH, producing a TH insufficiency. An attempt, in collaboration with colleagues to see if there was an association between low vitamin B₁₂ levels and myofascial pain, showed no difference in vitamin B₁₂ levels between persons with myofascial pain and healthy normal controls, though there were only 36 subjects in that study (Gerwin, unpublished data). However, B vitamins have been shown to reduce neuropathic pain.^{46–52} Furthermore, B-vitamin complex consisting of thiamine, pyridoxine, and cyanocobalamin, injected intrathecally into mice, potentiates acute morphine antinociception and attenuates antinociceptive tolerance, inhibits morphine-induced microglial activation, and suppresses the phosphorylation of the *N*-methyl-D-aspartate receptor-NR1 (NMDAR-NR1) to make NMDAR-NR1 subunit and protein kinase C (PKC) following chronic morphine treatment.⁵³ The NMDA receptor plays a critical role in the development of morphine tolerance.^{54,55} Protein kinase C modulates NMDA receptor activation and contributes to morphine tolerance. Phosphorylation activates the NMDA receptor, an action that is augmented by morphine. Suppression of the phosphorylation of the NMDA receptor and of PKC will reduce the activity of the NMDA and attenuate its ability to promote tolerance to morphine antinociception. Microglia also play a role in the development of morphine tolerance.⁵⁶ The proinflammatory cytokine IL- β is increased with microglial activation, and has the potential for activating the NMDAR. Thus, the B vitamins thiamin, pyridoxine, and cyanocobalamin given together may play a role in the management of chronic pain treated with morphine.

3.2. Vitamin D

Vitamin D is a prohormone that contributes to the regulation of calcium and phosphorus in bone. It is synthesized in the skin in the presence of sunlight (ultraviolet B light) and converted to 25OH-vitamin D in the liver. The ability of the skin to synthesize vitamin D diminishes with age. Ceglia⁵⁷ has reviewed the role of vitamin D in muscle function. Vitamin D receptors are present in muscle tissue, providing a means for vitamin D to play a role in muscle function. VDD produces a type II, fast-twitch, muscle fiber atrophy. These type II, fast-twitch fibers are contained in the muscles that are first recruited to prevent falls. Vitamin D receptors on the muscle are nuclear transcription factors that affect muscle cell proliferation and differentiation.⁵⁷ There are also nongenomic effects of cell surface vitamin D receptors that act on calcium entry in the muscle cytosol that affect contraction and relaxation of the muscle, as well as myogenesis and muscle type differentiation. Vitamin D polymorphisms have been associated with reduced muscle strength. Vitamin D is also associated with a reduction in the release of proinflammatory cytokines, and it

suppresses T cell responses. It inhibits the synthesis of prostaglandin E₂.⁵⁸ Thus, vitamin D can influence muscle pain and myofascial pain both by its direct effect on the muscle and by its indirect effect on nociceptive mechanisms.

VDD is a global epidemic. The 2001 to 2006 National Health and Nutrition Examination Study found that about 20% of children aged 1 to 11 years were vitamin D deficient. VDD in children was directly correlated with obesity.⁵⁹ Vitamin D levels may be low in northern and southern latitudes away from the equator, where the angle of the sun is below 45° for prolonged periods of the year, but VDD can be endemic in equatorial lands because cultural dress codes may lead to covering the body, and because the use of sunscreen blocks the ultraviolet B frequency needed for vitamin D synthesis in the skin. Powanda,⁶⁰ in a discussion of the relationship of vitamin D levels to chronic pain, notes that the racial discrepancy of vitamin D serum levels and pain between black and white people is not necessarily true, because black people have lower levels of vitamin D-binding protein, so that there is nearly equivalent bioavailability of vitamin D between white and black people. Hence, the observational studies that report an association between chronic pain and low vitamin D may be misleading, because polymorphisms of vitamin D receptors may mean that vitamin D levels may not give an adequate picture of bioavailable vitamin D. That said, there are good reasons to consider the surveys showing very low levels in vitamin D to be significant, as the levels can be very low, and they correlate with levels of pain. Studies of serum levels of vitamin D across populations and across various chronic musculoskeletal pain disorders show a consistent decrease in vitamin D levels, ranging from 26% to 93% of subjects with pain, but most studies show that the percent of persons with chronic pain and low vitamin D levels hovers about 60% to 70%. However, there are other studies that found no lower levels of vitamin D in subjects with chronic pain. Studies that show a correlation or an association of vitamin D with pain do not constitute evidence of causation. Moreover, studies of patients with chronic pain treated with vitamin D have not demonstrated a benefit with vitamin D supplementation.⁶¹ VDD is associated with a wide variety of nonskeletal disorders as noted in many observational studies. Yet, supplementation with vitamin D does not reduce the occurrence of these conditions or reverse them. This result has led to the consideration that low vitamin D may not be a causal factor in these conditions, but may occur as a result of them. In particular, conditions associated with an elevation of inflammatory mediators may be associated with a reduction in vitamin D levels. As stated, it is impossible with observational studies to make a causal relationship that inflammatory mediators result in lower vitamin D levels.⁶² Indeed, a single high-dose bolus of cholecalciferol significantly reduced TNF α and IL-6, but not other inflammatory mediators, indicating that vitamin D may regulate these cytokines rather than be regulated by them.⁶³

Vitamin D has been studied in chronic widespread pain. An association between VDD and chronic widespread pain, including FMS, has been shown, with an odds ratio 1.63; 95% confidence interval (CI), 1.20 to 2.23 ($P = 0.117$), based on a review of 12 studies. There was no difference between genders, despite the predominance of women with

chronic widespread pain. The odds ratio was higher when lower levels of vitamin D, 8 to 10 ng/mL were evaluated.⁶⁴ As with all observational studies, no causal relationship can be made from this data.

In other musculoskeletal disorders (which were not looking at myofascial pain, but in which TrPs could reasonably play a role), VDD was associated with knee pain and impaired knee function, and a nonsignificant reduction in lower extremity strength.⁶⁵ VDD has been shown to be directly correlated with chronic low back pain (LBP),⁶⁶ the pooled odds ratio = 1.60; the 95% CI 1.20 to 2.12; $P = 0.001$, the number of studies, nine. However, the correlation was significant only for women, and only for women in the Middle East and Mediterranean regions. This correlation was thought to be related to dietary habits and particularly to dress customs (veiling), sun exposure, physical activity, and obesity, although issues of osteoporosis, muscle weakness, and a bias in the articles reviewed could have skewed the findings. The authors considered that low vitamin D could be causal for LBP, but did not consider the possibility that people with LBP might be less active, more likely to be homebound, more prone to develop osteoporosis through reduced activity, and less likely to be exposed to sunlight.

Treatment effects from vitamin D supplementation have been varied and inconsistent. The association of chronic pain, especially musculoskeletal pain, and VDD is observational, and therefore no causal relationship can be inferred. Attempts to determine cause and effect in humans have been based on showing improvement with vitamin D supplementation in subjects with VDD. Attempts to demonstrate benefit from vitamin D supplementation have had mixed results. Further compounding the problem is that no suitable dose of vitamin D has been identified, and we do not know if different disorders require different doses. One goal would be to bring up the serum vitamin D level to between 50 and 70 ng/mL, but that is often not achieved when treating with 1000 IU vitamin D₃ per day. Some will treat with 2000 IU/d, and some will treat with 5000 IU/d. Treatment is compounded because if a pill is used, it must be taken with some fat, because vitamin D is poorly water soluble. A tablet taken with water, juice, or fat-free milk will not be well absorbed. Vitamin D in the form of a gel cap with oil is a better form to use. The results of treatment have been disappointing. No significant improvement in muscle strength, as measured by hand grip strength or in timed-up and -go (a common functional measure of lower body strength and balance), was seen with vitamin D supplementation.⁶⁷ The use of vitamin D supplementation for the prevention of falls and fractures is not supported by the literature, though the studies on this relationship are scant.⁶⁸ However, some randomized controlled studies do indeed show a significant reduction in falls risk, especially in individuals less than 75 years of age.⁵⁷ A nonsignificant trend toward pain reduction was found in one meta-analysis of over 3000 subjects of mixed pain etiologies, hospitalized and nonhospitalized, about half of whom were treated with vitamin D and about half were given placebo.⁶⁹

There is no evidence in the literature that vitamin D supplements are beneficial for the treatment of TrPs in persons with vitamin D serum levels that are normal (50 ng/mL or

higher), and no evidence that they are beneficial for mild insufficiency down to about 30 ng/mL. Moreover, there is scant evidence of benefit for persons with levels as low as 20 ng/mL. Below 20 ng/mL, there is an increased risk of secondary hyperparathyroidism that is reason enough to treat individuals with severe VDD (certainly for levels below 15 ng/mL). However, most if not all of the studies that have shown failure to improve with vitamin D supplementation reported only on treatment with vitamin D, and did not take into account that the subjects in the studies might have mixed deficiency states, including other nutritional deficiencies and other disorders, such as hypothyroidism. Patients with VDD seen in clinical practice, commonly may have mixed deficiency states that include iron deficiency, vitamin B₁₂ deficiency, and hormonal deficiency, ie, hypothyroidism. Moreover, vitamin D improves magnesium absorption in the jejunum, so that VDD may result in magnesium deficiency or inadequacy.⁷⁰ Replacement of vitamin D alone may leave an individual's magnesium deficient if dietary magnesium is inadequate. Magnesium deficiency may have consequences for muscle, including muscle weakness. The same is true for vitamin D and hypothyroidism (another condition made more likely in individuals deficient in vitamin D). Hence, treatment of the VDD alone can reasonably be considered as insufficient, so that it would not be surprising that there was little benefit for a cohort so treated. Clinically, some patients who had widespread myofascial pain and only VDD, responded quite well to vitamin D supplementation alone. In conclusion, a patient who has chronic myofascial pain syndrome of longer than 3 months duration should be evaluated for multiple deficiency states, and all deficiency states found should be corrected. In addition, treatment with vitamin D supplementation alone in a patient with normal vitamin D levels (30 ng/mL or higher) or with mild insufficiency, say 25 ng/mL or higher, should not be regarded as likely to be of benefit.

3.3. Magnesium

Magnesium (Mg²⁺) supplementation has been a favorite of people with chronic widespread pain or FMS, either taken alone or taken in combination with other substances, sometimes injected as nutritional supplemental “cocktail.” How much of this treatment is based on modern medical folklore is hard to determine, but Mg²⁺ supplementation has been a popular treatment in the FMS community for years, so much so that much of the literature of Mg²⁺ effect on pain is in the FMS literature. Given that many individuals with FMS have widespread MTrP pain, it is reasonable to consider the pain aspect of FMS, if not the fatigue, cognitive impairment, and the sleep disorder, as a MTrP pain issue, at least in part. Likewise, many of the comorbid disorders of FMS like temporomandibular joint dysfunction, migraine headache, and visceral pain syndromes have MTrPs as a significant component. Indeed, for those individuals with chronic and widespread MTrP-related pain, central sensitization has most certainly occurred, contributing to widespread pain, hypersensitivity, and allodynia. CPM and the supraspinal descending nociceptive modulation inhibitory and facilitatory pathways have been less intensively studied than central and peripheral sensitization. The data on peripheral nociceptive input from TrPs in

FMS are so strong,^{71,72} and the parallel underlying central sensitization of chronic MTrP pain to that of FMS is so great, that we may look carefully at the studies of Mg^{2+} in relationship to FMS pain and expect that we will learn something useful about MTrP pain.

Magnesium plays an essential role in a wide range of physiologic functions, including those in skeletal muscle. It is a cation that is second only to potassium in abundance in the body. It is involved in most metabolic and biochemical processes. It is a cofactor in an estimated 600 enzymatic reactions in the body. It is required for protein and DNA synthesis. It is estimated that as many as 60% of Americans do not consume enough magnesium and have some degree of magnesium insufficiency. Serum magnesium represents just 1% of the body's Mg^{2+} as magnesium is stored in other body tissues, including muscle, so that the estimate of inadequate magnesium levels in the general population may be understated. Moreover, most intracellular magnesium is bound to ribosomes, polynucleotides, and ATP, so that free magnesium levels are relatively low. Measurements of serum magnesium may not reflect tissue levels.⁷³ Magnesium is abundant in many foods, but processed foods are low in magnesium and boiling foods deplete magnesium. Hence, magnesium may not be plentiful in the diets of many people.

Magnesium is an antagonist to calcium (Ca^{2+}) in muscle. It is present in concentrations that are 10 000 times as great as Ca^{2+} concentrations in the resting muscle. Magnesium is bound to all of the Ca^{2+} binding sites on troponin C and myosin, and is displaced by Ca^{2+} after the latter is released from the sarcoplasmic reticulum. When there is too little magnesium in muscle, less Ca^{2+} is required to replace Mg^{2+} in the troponin-myosin complex, leading more easily to muscle contraction, and predisposing muscle to cramps.

Magnesium molecules block the NMDAR channel and prevent its activation, a critical step for the establishment of central sensitization and persistent (chronic) pain. Glutamate, an excitatory amino acid, displaces or removes Mg^{2+} from the NMDAR channel, thereby activating the NMDAR channel leading to the chain of events supporting pain chronicity.⁷⁴ It would seem logical that if Mg^{2+} were not displaced from the NMDAR, then pain might be alleviated. This thought may be behind the idea of using Mg^{2+} supplements in the treatment of chronic musculoskeletal pain.

Magnesium is required for the conformational change of myosin that takes place during contraction and relaxation. Myosin utilizes Mg ATP to produce the conformational change from straight to bent, the recovery stroke in the cycle. After the recovery stroke, myosin undergoes another conformational change back to straight. These changes constitute a pre- and postpower stroke process. Magnesium ATP binds to myosin in a process that releases phosphate and results in the hydrolysis of ATP. Mg^{2+} is thought to position the nucleotide within the active site of myosin for subsequent hydrolysis.⁷⁵

Magnesium levels in clinical studies were found to be significantly lower in patients with FMS than in control subjects in an analysis of elements in hair, along with lower levels of calcium, manganese, and iron.⁷⁶ Serum levels of magnesium have also been found to be lower in subjects with FMS than in controls,⁷⁷ but are not reliable as indicators of tissue levels of Mg^{2+} . Romano⁷⁸ found lower than normal serum levels of Mg^{2+} in patients with

FMS and/or myofascial pain than in controls, and advocated magnesium supplementation. Okumus et al⁴⁸ reported that the total myalgic score correlated inversely with serum magnesium in myofascial pain patients. However, serum magnesium levels correlate poorly with total body magnesium because magnesium levels are tightly controlled with only 1% of magnesium in the extracellular fluid and only 0.3% in serum.⁷⁹ These levels may be maintained in Mg^{2+} deficiency. These findings raise the question as to whether hypomagnesemia is actually underreported. On the contrary, serum Mg^{2+} levels may not reflect muscle Mg levels, which may be maintained even if serum levels are low.

Magnesium supplementation in patients with FMS using Mg^{2+} citrate 300 mg/d improved the tender point index, the Fibromyalgia Impact Questionnaire (FIQ) score, and the Beck depression index score. Additional improvement in most of FMS symptoms was found when magnesium citrate was given along with amitriptyline 10 mg/d.⁸⁰ Magnesium is commonly included in intravenous micronutrient therapeutic infusions, including Myers Cocktail among others. These infusions have been popular for years in treating FMS and chronic widespread pain. However, a randomized, placebo-controlled study showed significant improvement in both the placebo arm and the intravenous micronutrient arm when intravenous infusions were given weekly over 8 weeks. The tender point index improved in both arms of the study; there was no statistical difference between the outcomes of the micronutrient infusion and the infusion of Ringer's lactate.⁸¹ No other randomized, controlled, blinded, trials using Mg^{2+} to treat FMS were found by searching PubMed. Despite the interest in Mg as a treatment for FMS and musculoskeletal pain, no convincing data exist to support its use. The few studies that exist are small studies. There are no studies of magnesium supplementation for the treatment of MTrP.

Magnesium may play a role in muscle cramps as mentioned previously. However, studies of this relationship have shown mixed results. Magnesium supplementation was not shown to reduce the number of cramps except possibly in women who are pregnant.⁷³ A more recent study showed that muscle cramps were reduced from 90% to 10% in a cohort of pregnant women who were Mg^{2+} deficient when given a supplement of 300 mg of magnesium daily (100 mg of a multimineral tablet plus 200 mg effervescent magnesium in the treated group to just the multimineral tablet in the control group).⁸²

Magnesium may play a role in preventing age-related loss of muscle mass, but the studies that support this suggestion are mostly observational rather than randomized controlled studies.⁸³ Mg^{2+} was associated with improved physical performance in older adults in one randomized controlled trial, and was associated with the prevalence of age-related sarcopenia.⁸⁴ Mg^{2+} supplementation of elderly individuals whose Mg^{2+} intake was below the recommended daily allowance showed a significant improvement in the Short Physical Performance Battery, but not in isometric or isokinetic strength, in body composition, or in physical activity over the 12-week course of a randomized controlled trial in which the treated subjects were given magnesium oxide (equivalent to 300 mg bioavailable magnesium). There was no benefit in any of the outcome measures from supplementation in individuals considered to have an adequate magnesium intake.

Malignant hyperthermia is a condition in which there is a hypermetabolic response to volatile anesthetic agents, resulting in an elevation of temperature and muscular rigidity. The syndrome serves as a model for the persistent contraction of muscle fibers in the MTrP in some respects. Dantrolene, an effective treatment of malignant hyperthermia, is most effective when magnesium levels are above resting levels of magnesium. Higher levels of magnesium increase the binding of Mg^{2+} to the ryanodine receptor, thereby stabilizing the resting state of the muscle.⁸⁵ Thus, there is a rationale for the use of Mg^{2+} in the treatment of MTrPs in that a return to the resting state of the muscle could relax the taut band without which the TrP does not exist. However, this has not been shown to occur in subjects with TrPs, or has never been looked at in patients with TrPs, perhaps because higher doses of magnesium act as a laxative, and adequate levels are not achieved in clinical practice.

Transdermal magnesium chloride administered as a spray, applied to the extremity was reported by patient responses on the Revised FIQ SF-36v2 to be effective in reducing symptoms at 2 and 4 weeks, but this study was open, unblinded, uncontrolled, and problematic in having no objective outcome measurement with a strong possibility of bias on the part of the subjects. Moreover, Mg^{2+} levels were not measured in this study.⁸⁶ Magnesium lactate 400 mg/d was given to 12 elite athletes during a full season of play. Measures of muscle damage were obtained four times, before and during the season. Creatine fell during the second-time period, but increased by the third- and fourth-time periods. No other parameters signifying muscle damage changed. The authors suggested that based on their results, Mg supplementation might prevent muscle damage.⁸⁷

4. MECHANICAL PERPETUATING FACTORS

Mechanical stresses can be structural, postural, or the result of repetitive use. Structural stresses occur because of muscle overuse to compensate for muscle imbalances caused by body structure asymmetry. Structural asymmetries and joint laxity can be congenital or acquired, and postural mechanical stresses can occur as a result of stresses imposed on the body by ineffective body mechanics, whether the result of intrinsic body dysfunction or of extrinsic forces, such as poor workspace ergonomics. A few mechanical perpetuating factors discussed below illustrate these points.

4.1. Ehlers-Danlos Syndrome

Joint hypermobility is an important, yet often overlooked, cause of musculoskeletal pain. Generalized joint hypermobility is a manifestation of Ehlers-Danlos syndrome (EDS), a genetic collagen disorder or a heritable connective tissue disorder.⁸⁸ This discussion will not engage the issue of whether or not joint hypermobility is an entity distinct from EDS or not, nor whether there is such a condition as benign hypermobility syndrome. Suffice it to say that EDS may be an important cause of musculoskeletal pain, as well as pain and dysfunction from associated neurologic conditions like tethered cord syndrome, spinal cord compression, and posterior fossa abnormalities. A number of molecular defects are

associated with this condition, among them defects in fibrillar collagen. The clinical expression or phenotype of EDS may vary, even within families. The variation of presentation extends to musculoskeletal pain as well, so that individuals with EDS and reports of pain may have family members with some degree of joint hypermobility, but who have no pain complaints. On the contrary, some individuals with EDS have reported that they thought that everyone had chronic pain; therefore, they never considered it something to report.

The prevalence of EDS ranges between 6% and 57% for females and 2% and 35% for males, occurring in 1:5000 to 1:10 000 persons, with great variability geographically and among different ethnic groups. There is also great variability based on different criteria for the diagnosis. In particular, the diagnosis has usually been based on the Beighton criteria⁸⁹ (Box 4-1) that assesses nine items. A score of 5 or more is commonly considered to be diagnostic of joint hypermobility, but some researchers have used a score of 4 or 3 to make the diagnosis, and some are stricter and use a score of 6 or more. The Beighton criteria emphasize findings in the large joints, and do not assess hypermobility in small- to medium-sized joints except for the 5th metacarpophalangeal joint. Furthermore, associated physical findings such as skin hyper-elasticity, and others mentioned below, are often required to confirm a suspected diagnosis. The Beighton criteria take these other manifestations of a connective tissue disorder into account and relate them to other connective tissue disorders.⁹⁰ The Beighton criteria are simple to use and can be done quickly, so that they are a useful screening tool. They can be supplemented by examining for additional features as is appropriate to a particular individual. There are nine types of EDS, though by the Villefranche nosology, they are collapsed into six subtypes, but type III, the hypermobile type, is by far the most common one, and is also most likely to present with pain. Pain is common in subjects with EDS, identified by means of the McGill Pain questionnaire in 90% of 273 subjects with confirmed EDS.⁹¹

Box 4-1 Beighton criteria for joint hypermobility syndrome

Maneuver	Right Side	Left Side	
Dorsiflexion and hyperextension of the 5th MCP beyond 90°	1	1	
Apposition of the thumb to the volar aspect of the forearm	1	1	
Hyperextension of the elbow beyond 10°	1	1	
Hyperextension of the knee beyond 10°	1	1	
Forward flexion of the trunk with the knees fully extended so that palms touch the floor			1

The first four maneuvers are passive, the last is active. The total score is X/9, where X represents the number of positive tests.

.

4.2. Forward Head Posture

Forward head posture (FHP) is a significant risk factor for neck pain, temporal mandibular joint pain, and headache, as well as altered body mechanics. FHP drops the head, directing gaze toward the ground. The head must then be brought up to accomplish a horizontal gaze. This compensation has consequences for head and neck musculature that will be detailed below. Headache is likely to be the consequence of referred pain from both neck muscles and orofacial muscles, the latter affected by the posterior displacement of the mandible that occurs in FHP.

FHP lengthens the ventral neck muscles, shortens posterior extensor muscles, weakens those muscles that are at a mechanical disadvantage, and places mechanical stress on the cervical zygapophyseal joints. As one would expect, thoracic kyphosis that would bring the head forward is associated with excessive cervical lordosis.⁹² Flexion of the lower cervical vertebral segments is accompanied by hyperextension of suboccipital segments (OA-C1-C2) and shortening of the suboccipital musculature. Increased lower cervical flexion also increases the lower cervical neural foraminal areas, potentially relieving pressure on compressed cervical nerve roots.⁹³ Sternocleidomastoid muscle (SCM) thickness is increased, presumably because of tonic muscle contraction.⁹⁴ SCM activity is greatest in the fully flexed position, whereas middle trapezius muscle activity is reduced.⁹⁵ Rectus capitis posterior muscle activity is increased in FHP. These muscles are thought to stabilize the occipitoatlantal and the atlantoaxial joints,⁹⁶ but may also serve a proprioceptive function. Head position proprioception is impaired by FHP.⁹⁷ Static balance is also impaired by FHP, indicating that there is a more widespread effect of FHP on body balance mechanisms than just that affecting craniovertebral posture.⁹⁸ Postural balance has been shown to be altered in computer workers with FHP.⁹⁹ FHP and TrPs correlate positively with tension type headache (TTH).¹⁰⁰ Trigger points also correlate positively with FHP. This is an important aspect of TTH that needs to be included in the assessment of patients with TTH, as it affects treatment outcome. FHP is also associated with migraine headache.¹⁰¹

4.3. Other Mechanical Stresses Predisposing to Chronic MPS

Ergonomic factors have been well-documented as causes of muscle overuse and of MTrPs. These range from inappropriately designed work spaces to prolonged use of a keyboard (laptop or desktop computer). Prolonged, steady typing is clearly a precipitating factor, and shoulder muscle pain can start after as little as 30 minutes of typing.^{102, 103} Other

occupational stresses are known, among which is the well-studied tendency of playing various musical instruments to overload muscle. Sitting in ill-fitting chairs can lead to neck, shoulder, and back pain. Eyeglasses with an inappropriate focal length cause neck muscle strain and overload. Carrying a backpack over one shoulder or a heavy bag in one arm will cause the ipsilateral shoulder to be elevated, a well-known cause of levator scapulae muscle overload and pain at the upper medial border of the scapula. Degenerative joint disease or osteoarthritis of the shoulder, the hip, and the knee is associated with painful TrPs in the muscles associated with the affected joint. Post total joint replacement recovery can be complicated by TrPs in the periarticular muscles. Pain can be reduced and active range of motion increased following inactivation of TrPs in these muscles. Finally, psychological factors, particularly kinesiphobia and catastrophizing, two potential responses to chronic pain, can impede recovery.

Clinical Presentation

Patients frequently present in the clinic with reports of pain, often not knowing that they were hypermobile. They often report, however, that they have unusual range of motion and that they knew this when they were small children. They often enjoyed ballet or gymnastics, activities suited to those persons who are hypermobile. However, they are otherwise generally less involved in sports than their nonhypermobile counterparts.¹⁰⁴ Pointed questions about their range of motion are often necessary because they have accepted their range of motion as typical. Questions about headache, numbness, tingling, and their voiding frequency must be included, as tethered cord syndrome appears to be more common in patients with EDS, and can cause neurologic impairments such as sensory abnormalities, bladder dysfunction, motor disturbances, and can be associated with the base of skull abnormalities. Hyperreflexia of deep tendon reflexes is a sign that there may be spinal cord dysfunction related to tethered cord in these patients. There are, moreover, protean manifestations of this connective tissue disorder in addition to joint laxity. The so-called classic type of EDS, types I/II, is characterized by significant skin involvement in addition to joint hypermobility. The hypermobile type III is characterized by joint hypermobility and mild skin involvement. The distinctions are not always clear clinically, but there are specific collagen and gene abnormalities for each type. The classic type of EDS is associated with an abnormality of type V procollagen, and genes COL5A1 and COL5A2. There is a decreased amount of type V collagen in tissues. The phenotype is caused by a disturbance in the regulatory function of type V collagen.¹⁰⁵ The diagnosis can be confirmed by genetic testing for COL5A1 and COL5A2. If genetic testing is negative or unavailable, the diagnosis can be confirmed by skin biopsy. The hypermobile type is associated with a defect in Tenascin X and a genetic abnormality in gene TNXB. Both conditions are autosomal dominant. The clinical examination is usually sufficient for clinical management, and neither genetic testing nor skin biopsy is required. In hypermobility syndromes, molecular abnormalities exist in the constituents of the extracellular matrix (ECM) that result from defects in at least 19 different genes, in collagen

types I, II, V, and therefore in connective tissue.⁸⁸ The term hypermobility spectrum disorder is currently used to describe a wide range of presenting symptoms and severity of involvement in people with EDS.

The physical findings of patients with EDS-hypermobile type, in addition to hypermobile joints, include skin stretch marks; velvety, soft skin (so-called “cigarette-paper”); widened, atrophic scars; translucent skin with prominent blue veins; high-arched palate; lack of a frenulum associated with the ability to touch the tip of the tongue to the nose; dysautonomia with unstable blood pressure and often postural orthostatic tachycardia (POTS); skin and vascular fragility; and evidence of cardiac conduction defects. Manifestations of joint hypermobility include a predilection for “popping” joints, recurvatum of the knees and elbows to 10° or more, unusual and excessive joint hypermobility such that an individual may be able to wrap an arm around the back and then be able to touch the umbilicus with that hand, and equal feats of hip and lower limb excessive joint mobility movement. Pectus excavatum may be present. There is often excessive lumbar lordosis and thoracic kyphosis, and scoliosis may be noted. Marfanoid features are common. Pes planus on weight bearing indicates collapse of the longitudinal arch when standing. Hyperactive deep tendon reflexes, and possibly clonus, suggest CNS involvement, such as tethered cord, posterior fossa abnormality, or cervical spinal cord compression from occipital-cervical spine instability. There may be patchy sensory loss throughout the body. Involvement of the brainstem may result in the absence of the gag reflex. Small fiber neuropathy causing moderate to severe pain was found in 95% of a cohort of 24 subjects with EDS.¹⁰⁶ Ulnar nerve subluxation was found frequently in the one study that looked at that issue.¹⁰⁷

Pain is a common complaint in patients with EDS, although early studies of this association may have underestimated the prevalence of pain in EDS because hypermobility was often unrecognized and therefore underdiagnosed. Sacheti et al¹⁰⁸ published the first detailed study of pain in 51 subjects with EDS of different types. He found that musculoskeletal pain started in childhood or adolescence, progressively worsened to become chronic and then more widespread over time, primarily involved joints or joint regions, but also included the head and the abdomen. Later studies have confirmed these findings. Recent studies have shown that about 90% of individuals with the hypermobile type of EDS have chronic pain. Individuals with recurrent joint dislocation seem to have more pain. Ankle sprains are common with joint laxity and instability, leading to chronic ankle pain. Pain may be localized to one or more joints that have been repeatedly traumatized. However, there may be widespread joint pain as well. Myalgia, unrelated to specific joints, or perhaps more appropriately stated, relate to widespread joint laxity, occurs in addition to arthralgia. Pain tends to occur in three phases according to Rombaut et al¹⁰⁹: an early phase of acute, local pain due to joint and soft tissue injuries, occurring in the first decade of life. A second phase occurring over the next three decades is one of widespread musculoskeletal pain, and the third phase, later in life, is characterized by what the authors call maladaptive cognition, ie, catastrophizing and related psychological responses to pain, which tend to increase disability. In other words, musculoskeletal pain tends to progress from being more

acute and localized when patients are younger to being more constant and generalized, and therefore more disabling, as patients age. The most common pain report among patients with EDS is musculoskeletal pain. Joint pain, muscle cramps, tendinitis, headache, and fatigue are prominent symptoms.¹⁰⁴ Pain is both nociceptive and neuropathic, in almost equal proportions.¹⁰⁹

Atlantoaxial instability and tethered cord syndrome are two structural abnormalities of the spine and CNS that are common in EDS more so than in the general population. The former may present with headache, and the latter with low back, leg, and feet pain among other symptoms. Tarlov cysts are seen in patients with EDS, presenting with sacral and pelvic region and lower extremity pain. The diagnosis of Tarlov cysts is made by imaging studies. The most effective treatment is surgical removal or ablation of the cyst(s).¹¹⁰

Fatigue is commonly reported by patients with EDS. It may present in childhood as exercise intolerance, and in later life as delayed recovery from exercise. It is particularly associated with orthostatic intolerance that was present in almost 75% of subjects with EDS-hypermobile type.¹¹¹ Patients with reports of fatigue may be misdiagnosed with chronic fatigue syndrome before EDS is identified as an underlying condition. Sleep disturbances, muscle weakness, and medication may also contribute to the symptom of fatigue. POTS is a significant finding in patients who have EDS-related fatigue. Fatigue is positively correlated with pain.

The etiology of pain in patients with EDS is not always apparent, as Syx et al⁸⁸ point out. Gross joint trauma and microtrauma to joints that are unstable cause a nociceptive response that is certainly an accepted mechanism of injury. Myofascial pain syndromes, not mentioned in the literature about EDS pain, occur as muscles attempt to stabilize lax, unstable joints, and because of muscle stress resulting from muscle-imbalance scoliosis leading to muscle overuse syndromes. Injury to peripheral nerves from subluxation and small fiber neuropathy are other causes of neuropathic pain in patients with EDS.^{106, 112} Spinal cord compression in the neck or at the occipital-atlas junction results in instability of the cervical spine that can cause neck and back pain. Persistent or recurrent nociceptive and neuropathic pain results in peripheral and central sensitization with resultant hypersensitivity and allodynia. Kinesiophobia adds an additional pain augmenting factor.

Changes in the ECM resulting from defects in collagen, glycoproteins, and proteoglycans that cause connective tissue dysfunction can also be a major factor in the development of neuropathic pain.⁸⁸ In addition, some sequestered components of the ECM can act as damage-associated molecular patterns that are identified by pattern recognition receptors in the immune system. The release of proinflammatory cytokines that initiate or maintain nociceptive and neuropathic pain may then follow.

Management of EDS is mostly symptomatic and corrective of structural abnormalities wherever and to what extent is possible. Skin fragility requires skin protection. Bleeding abnormalities can be treated to minimize spontaneous hemorrhage. Physical therapy is useful to treat muscle hypotonia and delayed motor involvement, to treat musculoskeletal pain, and to guide individuals in strengthening programs designed to restore effective movement patterns. Ring splints are useful for unstable finger joints. Activities that can

unduly stress joints are not advised. Functional movement modifications may help some individuals to more safely pursue certain sports activities. For example, if throwing a soccer ball overhead into plays risks shoulder dislocation, the ball should be thrown from the chest without raising the arms over the head. Cognitive behavioral therapy, dialectical behavioral therapy, or other psychological approaches can help avoid some of the problems of maladaptive psychological responses. Graded and progressive aerobic exercises can lead to effective strengthening that can support unstable joints. Treatment of TrPs can reduce muscle pain, and can also help reduce functional scoliosis.

5. CHRONIC PAIN, ALTERED CNS FUNCTION, AND MALADAPTIVE MOVEMENT PATTERNS

Patients who have chronic myofascial pain syndromes can develop altered movement patterns that compensate for restrictions or impairments of normal movement and that constitute maladaptive movement patterns. Maladaptive movement patterns have consequences that affect the CNS. Chronic or recurrent LBP induces changes in the primary motor cortex of the brain that are associated with increased pain and with altered sequencing of muscle activation patterns.¹¹³ In healthy individuals, increasing lumbar lordosis activates the medial multifidi musculature to a greater extent than the iliocostalis muscles. In patients with LBP, the paraspinal muscles tend to be activated in toto as a group, rather than sequentially and discretely. Brain mapping with transcranial magnetic stimulation in patients with LBP shows reorganization of the motor cortex with loss of differential activation of selected paraspinal muscles, consistent with the observation of mass activation of lumbar paraspinal muscles instead of discrete activation of particular muscles.¹¹⁴ This effect is directly related to increased severity of the LBP.¹¹⁵ These results of neuroplastic changes in the CNS alter the responses to nociceptive input in the spinal cord, in subcortical structures, and in the somatosensory and motor cortices of the brain. As can be imagined in the situation of LBP, these changes may result in the persistence of pain by the development of hypersensitivity and by promoting maladaptive motor responses that could aggravate and amplify pain responses and thus lead to persistent (chronic) pain. These changes may persist even after the initial insult has passed, and despite healing of peripheral tissues, just as the TrP does. The importance of these changes lies in their potential contribution to the transition from acute to persistent pain, to amplification of pain, and to altered mechanical function. In short, the CNS changes may explain why therapies directed only at peripheral structural and pathophysiologic dysfunctions that cause acute musculoskeletal pain may not be beneficial in all patients.¹¹⁶

The primary motor cortex has a rich array of connections to cortical regions like the primary and secondary somatosensory cortices, the prefrontal cortex, and subcortical regions like the thalamus as well. These connections play a critical role, because the recovery of effective motor function is dependent on sensory input; eg, on input from the S1 sensory cortex.¹¹³ These connections are important because effective motor function cannot take place except when motor cortex function is integrated with sensory input.

Appropriate motor function requires proprioceptive input, and is integrated with auditory, visual, and vestibular input. Impaired sensory function results in ineffective motor control. The implication of sensorimotor integration is that sensory stimulation plays an important part in recovery from motor deficits, that continued nociceptive input degrades motor function, causing weakness among other impairments, and that rehabilitation that focuses solely on motor function is not as effective as rehabilitation that addresses both sensory and motor function.¹¹⁷

Silfies et al¹¹³ postulate that chronic pain induces anxiety and hypervigilance about potentially painful movements, activates the parietal cortex that in turn amplifies the pain experience via its effect on the sensory cortex, producing abnormal patterns of movement. Moreover, the cortical mechanism of “attention switching” associated with fear of movement, which is a prefrontal cortical function, could lead to cognitive fatigue and a reduction in prefrontal cortical influence of sensorimotor integration. Depression, often associated with chronic pain, can increase the perception that nociceptive input is unpleasant and painful. Finally, the integration of altered sensory input with motor intention and movement leads to maladaptive motor patterns that may produce biomechanical stress and more nociceptive input from further muscle overload. These factors lead to the implication that rehabilitation of the patient with persistent musculoskeletal pain must include therapeutic modalities that target the disrupted and maladaptive sensorimotor communication. Conventional therapy directed primarily at strengthening muscle through exercise and through reducing local muscle pain, by, for example, TrP inactivation, will not correct the dysfunction of altered sensorimotor coordination, and therefore, may be ineffective in treating some patients with persistent pain. Specific treatments that target sensorimotor retraining, such as feedback-controlled movement activation exercises, or therapeutic or functional electrical stimulation,¹¹⁷ can help restore the normal integration of sensory and motor information and function. Targeting fear avoidance, catastrophic thinking, and depression further help restore normal CNS functioning. These approaches go beyond the usual, conventional approaches of local treatment of painful conditions such as LBP and move therapy into the realm of addressing hitherto neglected factors that lead to the persistence of pain.

Altered muscle activation patterns are also seen in femoroacetabular impingement syndrome resulting in disturbed muscle synergy. Maladaptive muscle contraction of paraspinal muscles to “stabilize the spine” and minimize spinal movement and pain in people with chronic LBP is directly correlated with pain catastrophizing more than with pain intensity.¹¹⁸ Experimentally produced LBP through the injection of hypertonic saline into low back paraspinal muscles resulted in greater muscle tightening (stabilizing the spine) in subjects who demonstrated pain catastrophizing compared with those who did not pain catastrophize, despite the lack of any difference in perceived pain intensity.¹¹⁹ These studies show that in addition to the effects of persistent pain, the psychological response to acute and to persistent pain affects motor function and can lead to maladaptive motor patterning. These studies, and others, demonstrate that muscle pain and joint pain directly and indirectly alter movement patterns, and that they can lead to more pain

through muscle overload. Unfortunately, there are few studies of TrP pain syndromes in association with maladaptive movement patterns, but I think that it is likely and believe that many of my chronic, difficult-to-treat patients with myofascial pain suffered from this complication. One notable study is that of Lucas et al¹²⁰ that showed that latent TrPs in the shoulder girdle muscles alter the normal sequence of muscle activation pattern in arm abduction.

6. OTHER PERPETUATING FACTORS

Three mechanical perpetuating factors have been presented that are not often discussed in the myofascial pain literature as well as five metabolic perpetuating factors. There are a number of other perpetuating factors that have been covered in great detail in the past,^{3,121} but that need to be reviewed for effectively evaluating and treating patients.

6.1. Iron Deficiency

Iron is required for the production of energy, and iron deficiency is one predisposing cause of a hypometabolic state and of refractory TrPs. There is only one published study that looked at this issue,⁴⁸ and it found no difference in serum iron levels between patients with myofascial pain syndrome (MPS) and healthy control subjects. However, the criterion for entry into the study was simply one or more TrPs in a shoulder muscle. There were only 38 subjects with MPS of whom 34 were female. It is doubtful that this study was powered well enough to detect changes in chronic myofascial pain. Some striking examples of the effect of iron deficiency have been noted in patients with persistent MPS. One example is a woman with MPS refractory to all usual effective treatments who had no stainable iron on bone marrow examination. She recovered uneventfully after iron replacement treatment. Iron deficiency is common among women because of menstrual bleeding. Serum iron levels below 20 ng/mL should be considered suspect for deficiency. Men are not typically iron deficient except in cases of a malignancy, or GI tract blood loss. Vitamin C chemically reduces iron and thereby facilitates its absorption, so iron supplementation should be accompanied by vitamin C supplementation.

6.2. Protozoal Infestation

Infestation by amoeba and some other parasites like fluke can cause diffuse myalgia and TrP pain. Exposure occurs when swimming in infested ponds or streams. Diagnosis is suggested by a history of exposure and confirmed by stool testing for ova and parasites. Clinically, the author of this chapter has never seen MPS associated with giardia or tapeworm infestation.

6.2. Sleep Deprivation

Sleep deprivation has long been known to be associated with muscle pain. Sleep apnea and restless legs syndrome are two conditions associated with a predisposition to muscle pain

and to refractory myofascial pain syndrome.

Psychosocial Considerations

Leslie F. Taylor and Jennifer L. Freeman

1. INTRODUCTION

Pain is both an intensely personal experience shaped by life events and a universal human experience conceptualized by era-specific norms. In prior times and in other places, pain has been diagnosed as a spiritual problem and treated as such. In the modern Western world, the origins of and the treatments for pain were forced into a purely biomedical box. As science advanced and the bioanatomic origins of pain were identified, the biomedical model rightfully gained prominence. The pain experience was defined in physical terms and considered objective and measureable. Pain was considered directly proportional to tissue injury. One of the downsides of this scientific perspective was the compartmentalization of pain management: physical pain managed by one team, psychological pain by another. The social, spiritual, and mind-body aspects of the pain experience were deemphasized. Now, fueled by more refined testing instruments as well as the acceptance of the phenomenologic nature of pain, the most appropriate model for the diagnosis and treatment of painful conditions is a biopsychosocial one. Myofascial pain, especially when accompanied by other painful conditions or perpetuated by factors discussed in Chapter 4 of this text, can be complicated and sometimes even persistent. For any patient experiencing pain, and even more importantly for those experiencing persistent or unexplainable pain, clinicians must be sensitive to the thoughts, emotions, behaviors, and social interactions that can either improve or worsen outcomes.

In the mid-1960s, Melzack and Wall introduced a new theory on the mechanisms of pain, later named the gate-control theory, which led the way for advancing pain sciences research.^{1,2} Concurrently, George Engel³ pioneered efforts to respond to the pervasive state of dehumanized medical care that he attributed to the dualistic nature of separating the body and mind, the excessively reductionist orientation of medical thinking that viewed the body as a machine, and the lack of humanity afforded to both the practitioner (the detached observer) and the patient.⁴ The biopsychosocial model, guided by sociology's Systems Theory,⁵ resulted from Engel's work. Current culture and evidence supports this

more integrated approach. Although many musculoskeletal clinicians consider pain from a broader biopsychosocial point of view, actually practicing from such a theoretical base remains challenging.

As demonstrated in the preceding chapters, tremendous gains have been made in understanding the biological initiators of pain, how to diagnose its source, and in many cases, successfully treat it. Clinicians, on average, are well educated and well prepared to assess and manage physical factors related to patient disability.⁶ Some have evolved past a strict biomedical mind-set and apply—or at least aim to apply—a broader biopsychosocial view with regard to managing patients with persistent pain.⁷ However, this evolution is confounded by the fact that the majority of practicing clinicians were educated and trained in the biomedical model, with the “softer skills” of considering psychosocial factors, communication, and facilitating rapport-based patient–client interactions receiving far less attention, and at times, far less respect. Although clinicians may acknowledge and endorse the role of psychosocial variables, many feel a true lack of preparedness to address these concerns. Professional education courses addressing psychosocial concerns are often truncated and are rarely integrated across curricula, and postprofessional courses are almost always skills focused. So, despite evidence supporting a biopsychosocial philosophy of practice, clinicians feel ill-equipped to effectively manage patients with complex or persistent experiences of pain.

Decades of research have attempted to clarify, measure, or explain various aspects of the biopsychosocial model.⁴ Although applying a reductionist approach to this model is antithetical to its intent, efforts are rightfully focused on finding ways to determine and understand how different aspects of the biopsychosocial model contribute to pain, how they interact, and which treatment interventions may be most effective. It is far beyond the scope of this chapter to even come close to mentioning, much less addressing, all of the complexities of this topic. Rather, this chapter provides an overview of some psychological and sociological theories and themes foundational to the experience of pain that may help guide treatment and improve outcomes.

2. PSYCHOLOGICAL AND SOCIOLOGICAL OVERVIEW

Prior to considering biopsychosocial strategies for the comprehensive management of patients with pain, a brief review of several major psychological and sociological theories and constructs is in order.

2.1. Psychological and Sociological Frameworks

The relationship of human thought, emotion, and behavior with the outside world has been a topic of study for centuries. Early behaviorists discovered that responses can be modified by external events. Cognitive-behaviorists rejected a purist form of behaviorism and integrated with it the power of thought in human experience and its role in shaping behavior. Existential-humanist theories focused on whole-person care and the importance of subjective meaning. And third-wave behaviorism has seemingly attempted to reunite

psychology with philosophy to outline strategies for navigating life's difficulties with realistic expectations. Modern healthcare professionals, cognizant of the need for biopsychosocial care, find it useful to combine what could be seen as aspects from many viewpoints with more nuanced and dynamic models of the interplay between emotion, thought, behavior, social interaction, and meaning. The following concepts are far from an exhaustive list of theories and themes that can impact the diagnosis and treatment of myofascial pain and dysfunction. For more on psychological frameworks and concepts, refer to additional resources.

2.2. Behavioral Learning Theories

Classical Conditioning

In 1889, while researching digestion in dogs, Ivan Pavlov formed the psychological theory of classical or respondent conditioning.⁸ In the oft-cited experiment, a bell rung prior to feeding over time initiated an involuntary canine response to salivate prior to the arrival of food. When food regularly did not appear after the bell, the conditioned response waned and eventually ceased. This “learning” and “extinction” was thought to apply universally to human behavior. Research suggests that classical conditioning can amplify pain (associative learning), but conclusions about whether or not classical conditioning can elicit pain remain under consideration.⁹

Operant Conditioning

In the 1950s, B.F. Skinner's theory of operant conditioning supported the premise that behavior could be altered because of consequences as well as stimuli.¹⁰ The theory states that behavior followed by positive or negative reinforcement increases the probability of that behavior, whereas punishment reduces it. Fordyce^{11,12} and Fowler et al¹³ applied this theory in a behavioral model of pain, highlighting the importance of the stimulus response of learning in developing and maintaining chronic pain. Fordyce began exploration of the now widely accepted distinction between the factors that initiate pain and the factors that perpetuate pain.¹⁴ The intent of integrating operant conditioning theory into musculoskeletal therapeutic interventions is to increase the occurrences of healthy behaviors through positive reinforcement and reduce the frequency of pain behaviors by removing reinforcement.¹⁴

2.3. Cognitive-Behavioral Themes

Self-Efficacy and Locus of Control

Albert Bandura's theory of self-efficacy, part of social cognitive theory, is the belief in one's ability to influence events that affect one's life and the way these events are experienced.¹⁵ In a systematic review of the role of self-efficacy on the prognosis of individuals with

chronic musculoskeletal pain, higher self-efficacy was associated with greater physical function, physical activity, health and work status, and satisfaction. Likewise, higher self-efficacy is associated with lower levels of pain, disability, disease activity, depressive symptoms, the presence of fibromyalgia tender points, fatigue, and presenteeism (at work, but not functioning at top level).¹⁶ Somewhat counter to a biomedical focus on limited capacity as a result of injury/disease, Bandura emphasizes human capacity rather than human failings and dysfunction. In the same way that physical strength or endurance can be trained and improved, Bandura proposes that self-efficacy can also be strengthened, which, in turn, can improve function.¹⁷ Low self-efficacy is associated with greater reports of pain, anxiety, and reduced ability to distract attention away from symptoms. Higher self-efficacy is associated with lower reports of pain and anxiety, higher resilience, and an ability to distract attention from sensations and to shift the meaning of pain/change the interpretation.¹⁸ More optimistic, the person who is motivated from this perspective is able to make more effective management choices.

In the mid-20th century, Julian Rotter¹⁹ developed a social-learning theory of personality that included the concept of locus of control (LOC). LOC identifies the degree to which people believe they can control the events in their lives. Individuals with a strong internal LOC believe that they can effect change in their lives, whereas those with a strong external control LOC believe that something external to them is in charge of their lives. Rotter intended LOC to be considered as a continuum, not a static dichotomy, as a person's learning can influence their perceptions in various situations.²⁰

The application of this conceptual frame to health behaviors led to the development of a health-focused locus of control (HLOC).²¹ HLOC refers to an individual's expectations regarding whether health is controlled by one's own behaviors (Internal HLOC), or by external factors including chance, luck, and fate (Chance HLOC), or by powerful others, including healthcare providers (Powerful Others HLOC).²² Within each of these loci, the individual demonstrates behavioral, cognitive, decisional, and informational control reinforcing each internal world view. Stronger Internal HLOC correlates with better mental and physical health and more proactive health behaviors.^{23,24} An individual with stronger Chance HLOC believes that he or she has very little, if any, control over his or her musculoskeletal pain, and may adopt more pessimistic attitudes and approaches that lead to poorer choices and reinforce this belief state.

Self-efficacy is also related to HLOC, it and impacts how stress is perceived and managed. Lower self-efficacy, combined with low Internal HLOC, is correlated with higher illness-related psychological distress, higher levels of psychological and physical problems, and increased vulnerability to external influences, resulting in increased stress responses.²⁵ Multimodal interventions associated with increasing self-efficacy and Internal HLOC and lowering Chance HLOC have been shown to predict better outcomes for patients with chronic back pain.²² Also, patients with chronic pain can increase their Internal HLOC while still maintaining their positive expectancies related to the impact of the practitioner on their pain. In fact, trust in the practitioner (Powerful Others HLOC) can support the

adoption of effective pain management behaviors, and its absence can be detrimental.²⁶

Meaning/Beliefs/Illness Perceptions

Developed in response to a particular event or over a lifetime, health beliefs and meanings are adopted on the basis of experience. They support the person's perceptions of (1) their own personal vulnerability to the health concern, (2) the medical and social consequences of being ill or having the health problem, (3) how effective behaviors can be in reducing the risks associated with it, and (4) how barriers can be overcome to adopt those helpful behaviors.^{27, 28} An individual's beliefs and perspectives about a health problem are learned and evolve from a myriad of sources. Past experiences with health problems, research on the Internet, prior healthcare interactions, and prior injury-related education combine to form a complex system of beliefs about health and pain. Additionally, the meaning the individual attributes to the pain, and the theories of the pain's origins and why it persists are foundational to illness perceptions.

Levanthal's Common-Sense Model of Self-Regulation, also known as the Self-Regulation Model of Illness, centers on the individual's beliefs about the illness threat.^{29–31} In studies addressing chronic pain, strong associations exist between specific illness perceptions about pain, function, psychological morbidity, provider-focused frustrations, medication use, and health status.^{32–34} Self-regulation, both helpful and hurtful, of illness beliefs is reinforced through every interaction. The ability to strengthen physical self-regulation is achieved through shifts in and refinement of the belief system through positive reinforcement.^{35, 36} Related to the pain experience, Sauer and colleagues identify four dimensions to address: nociception, pain perception, suffering, and pain behavior.³² Self-regulatory strength and autonomic nervous system regulation are enhanced, and physical and psychological symptoms improved, through carefully ordered and managed biopsychosocial interventions.^{31, 32, 37} Self-regulation is self-efficacy actualized and can be trained in patients with myofascial pain to improve outcomes.

Cognitive Distortions

Within the category of illness perceptions are cognitive distortions, a concept from Aaron Beck's Cognitive-Behavioral Therapy (CBT),³⁸ which refer to various biased, exaggerated, or irrational ways of thinking.^{39, 40} Ineffective thought patterns can lead to and perpetuate anxiety, low self-esteem, low self-efficacy, and depression. Cognitive distortions are experienced by all people and are particularly relevant in the lived experience of the person with persistent pain.⁴¹ Building on meaning and beliefs, cognitive distortions such as somaticizing and catastrophizing are common thought or belief responses to pain that can increase pain behaviors. "Somaticizing tendency is the predisposition to be more aware of, and to worry about common somatic symptoms. It is characterized by (1) a constant scanning of the environment for threats (hypervigilance), (2) a tendency to focus on certain relatively weak and infrequent body sensations, and (3) a predisposition to intensify

somatic sensations, making them more alarming, noxious, and disturbing.”²⁷ Catastrophizing is fearing the worst possible outcome of the current concern. Catastrophizing can lead the individual to identify uncomfortable pain experiences as unbearable or impossible.²⁷ Overgeneralization, where a general conclusion is surmised from a single piece of evidence with the expectation that it will happen over and over again, is highly correlated with disability. Other examples of cognitive distortions include control fallacies (identification as a helpless victim of fate or responsible for everything), filtering (focusing only the negative aspects of a situation), and polarized thinking (the “I am perfect or I am failure” dichotomy with no middle ground to allow for life’s complexities).^{42, 43} A person’s maladaptive thinking, belief in, and reliance on cognitive distortions about pain may lead to poor coping, increased pain and suffering, and greater disability.¹⁸

2.4. Existential-Humanistic Themes

Another mid-century reaction to the impersonal nature of behaviorist learning theories (as well as the deterministic psychotherapy of Sigmund Freud), humanistic psychologists like Abraham Maslow and Carl Rogers stressed the importance of the subjective experience of life with all of its psychological concerns. For the modern clinician, aspects of this branch of psychology can promote a positive therapeutic interaction including patient effort toward growth and improvement and away from pathology and pain.⁴⁴

Patient-Centered Care

Now considered a hallmark of Western biopsychosocial care,⁴ the concept of person-centered or patient-centered care was introduced by Carl Rogers decades before Engle.^{45, 46} Person-centered care contrasts with the historical biomedical model of patriarchal healthcare in which the physician directs care, and the patient is expected to oblige. In person-centered care, healthcare professionals are encouraged to recognize the patients’ perspectives, respect their choices, and continually consider their values and goals.⁴⁷ Person-centered approaches are not only important in clinical care but show promise for improving research and better-informing clinical education.⁴⁸ Person-centered care does, however, have its drawbacks. Patient definitions of successful treatment may be lofty and difficult to achieve.⁴⁹ In these cases, the management of expectations may be possible only with persistent education communicated with compassion and understanding.

Nonpathologic Approach

In seemingly stark contrast to the biomedical model, Freud’s psychoanalysis, and even CBT to an extent, one humanistic approach to improving health outcomes is focusing on systems that support growth and performance instead of ones that treat or manage pathology. Recognizing the breadth of human experience, humanistic psychology argues for reducing the labeling of thoughts, emotions, and behaviors as pathologic in a healthcare setting.^{44, 47} Patients worried about clinician judgment of their actions or internal

experiences may understandably respond defensively to being told that their thoughts are irrational, that their emotions are exaggerated, and that their behaviors are keeping them in pain. Alternatively, they may also disengage from treatment. Instead, demonstrating understanding that many responses to pain are reasonable, given the situation, a clinician can gently guide patients to focusing on the most helpful responses. Even normalizing the fact that pain is a universal experience of the human condition and that ineffective responses to it are typical can be helpful in reducing the perceived threat of pathology for some patients. Validation and acceptance (see below) can also be helpful tools for applying a nonpathologic approach to helping patients in pain.

Values and Meaning

Personal growth and existential meaning can play a positive role in some patients with painful conditions. Similar to cognitive-behavioral theories, humanistic and existential psychology describe and explore the personal existential philosophies that provide meaning to individuals' lives.⁴⁴ Depending on the meaning patients ascribe to their pain, they can experience more distress or improved resilience, even posttraumatic growth.⁵⁰ Patients who successfully improve their self-awareness and self-knowledge, who adopt or move toward an internal LOC, and who adapt their behavior to maximize actions that align with their values may experience more personal meaning in their treatment than patients who do not.

2.5. Third-Wave Behavioral Themes

More recently, several other behavioral therapies, born out of the perceived deficiencies of pure behaviorism and CBT, could hold promise in improving outcomes for people with both psychological and physical pain.⁵¹ These newer approaches, including Acceptance and Commitment Therapy,⁵² Dialectical Behavioral Therapy,^{53,54} and others, depart from classical CBT in that they accept distortive thoughts and negative emotions as a universal part of the human experience, not a departure from mental health that must be corrected to improve outcomes. Integrating many person-centered concepts from a humanist perspective with the effective strategies of CBT, these methods are usually quite palatable to even highly sensitive patients.⁵⁵ From this theoretical acceptance of difficult emotions and thoughts, patients are encouraged to note the realities of their internal experiences, allow them, and shift their behaviors toward those that support autonomy and effective navigation of life's inevitable difficulties. Applied to physical pain (and the psychological and emotional pain that so often accompanies physical pain), the following concepts have been shown to help disrupt the connection between fear and avoidance, mitigate catastrophizing, and improve symptoms of depression associated with chronic pain.⁵¹ More research is needed to explore the potential benefits of these psychological approaches in treating patients with painful conditions, including myofascial pain.

Mindfulness and Meditation

A common theme of many third-wave behavioral therapies is the inclusion of a mindfulness and/or meditation component. Both mindfulness and meditation can be effective strategies for improving outcomes for people experiencing myofascial pain. Although related and often used interchangeably, mindfulness is the focus of attention on the present moment, whereas meditation is typically a more formal practice used to train the mind to witness thoughts, emotions, and sensations without attachment or aversion. A variety of methods exist for each, which allows patients to choose one that suits their preferences. Mindfulness training and meditation have been shown to improve pain modulation, reduce perceived pain intensity and unpleasantness, reduce patient reliance on opioids, and reduce sympathetic arousal; both can be effective for assisting in short- and long-term acute and chronic pain management.^{56–60} Even when practiced for only 4 days, meditation has been shown to reduce perceived pain intensity by 40% and perceived unpleasantness by 57%.⁵⁶

Acceptance

Psychological acceptance of the experience of pain can be key in both tolerating pain and improving pain and disability outcomes. Furthermore, acceptance as a strategy to improve emotion regulation in response to pain can reduce self and social stigma.⁶¹ Acceptance, like many psychosocial strategies for managing painful conditions, can be easily misunderstood and dismissed. Acceptance is only the acknowledgment of the reality of pain and its consequences.^{62–64} It is not submission or surrender to pain, but rather, it is a willingness to integrate it into adaptive and effective behavioral decision-making processes.^{64,65} Acceptance strategies can mitigate perceived discomfort and unpleasantness with painful stimulus,⁶⁶ and it has been shown to be a helpful psychological tool in the management of chronic pain as well.⁶⁷ An outcome measure (the Chronic Pain Acceptance Questionnaire) has been created to help clinicians assess progress toward pain acceptance.^{65,68} Curiosity about the particulars of a pain experience (eg, location, quality, timing) and an individual's responses to them is one way to engage an attitude of acceptance in a clinical setting. Gentle curiosity, by nature, focuses attention on the object of interest in a pleasantly anticipatory way (as opposed to anxiety, which is negatively anticipatory) that may reduce urges to ignore, control, or fight the discomfort.

Validation

Validation is more than empathy⁶⁹ and is key to developing a therapeutic alliance by creating safety of information sharing by the patient. Superficial validation is simple interest and active listening. Deeper validation happens when clinicians demonstrate that they can see the positive intent behind even ineffective responses to pain (eg, “It makes sense that you wouldn’t want to go for walks anymore now that your back hurts so much—your body is just trying to protect itself.”). Full validation, coupled with unconditional positive regard and person-centered care, communicates the message that the clinician truly believes that the patient is doing the best he or she can, given the circumstances.^{62,63,69} Validation is

best used early in establishing a therapeutic alliance to avoid the resistance and patient defensiveness that may occur when strategies focusing on behavioral change are used before establishing validation and mutual understanding.^{70,71} From the solid ground of feeling totally understood and accepted as they are, patients can take the first steps toward change. Of course, the level of validation that a clinician can offer during any specific patient interaction is dependent on the clinician's ability to remain grounded in authenticity and genuine compassion while doing so (see Self-Care).⁶⁹

2.6. Sociological Theories

Stigma

Stigma, the disapproval of a person or group based on social characteristics perceived to differentiate them from other members of society, was first considered by Emile Durkheim in the 1890s,⁷² and it was further conceptualized as a phenomenon by Erving Goffman in the mid-20th century.⁷³ Goffman's theory of social stigma laid the groundwork for medical sociology, which supported the labeling of patients with persistent pain as "deviant."⁷⁴ This "deviance paradigm" (shame) was confronted by an "oppression paradigm" (blame),^{74,75} which rightfully placed attention on those who stigmatized and labeled others, including healthcare providers. Link and Phelan⁷⁶ continued the conversation by focusing on power. Power differentials are particularly strong across all aspects of the healthcare experience and are reinforced on macro (health system), meso (organizational), and micro (individual) levels.⁷⁷ Stigmatization of illness is a matter of social injustice on a societal level,⁷⁸ and it can reduce help-seeking behavior on an individual level.⁷⁹ Disease and disability stigma is harmful, distressing, and marginalizing to individuals living with pain and leads to negative outcomes, including distress and social isolation.^{80,81}

Attribution Theory

As previously noted, a negative consequence of the biomedical paradigm is that individuals with unexplainable or persistent pain are often stigmatized by clinicians whose care they seek. The stigma in this case may result from blaming patients for their experience, known formally as attribution theory.⁸²⁻⁸⁴ Attribution theory describes how a clinician forms causal judgments on the basis of the assessment of the patient.⁸⁵ The practitioner can assign blame and attribute the onset and continued impacts of symptoms to something caused and controlled by the patient. Attributing causation to the patient has been associated with the practitioner demonstrating greater anger and less sensitivity to the patient, which can lead to missed diagnoses, undertreatment, or ineffective treatment protocols, severely damaging the therapeutic relationship and putting the patient at risk.^{82,86}

2.7. Complexity of the Psychosocial Experience of Pain

Clearly, no one model or set of psychological concepts is sufficiently broad enough to

manage all psychosocial factors associated with painful conditions of any kind. For a century, behavioral therapies have expanded to account for more and more of the human experience of the interplay between inner and outer perception, and they continue to evolve today. Operating from a biopsychosocial perspective requires a genuine understanding of each patient's personal experience, beliefs, and habitual emotional and behavioral responses to pain. Combining this understanding with knowledge of the above concepts can help clinicians understand and address the psychosocial factors of patients' pain that may affect the plan of care or clinical outcomes.

3. PATIENTS LIVING WITH PAIN

3.1. Common Affective Responses to Pain

Individuals living with pain experience a myriad of emotions and emotional responses that can impact their health trajectory. In considering mood, causal pathways have yet to be fully explained. However, low mood is correlated with the occurrence and persistence of pain symptoms, and its impact on the disability that follows appears to be even greater.^{27, 87} Depression significantly reduces the success of a multidisciplinary treatment of patients with chronic myofascial pain.⁸⁸ Emotional depressive symptoms vary from a sense of demoralization and sadness to suicidal tendencies. Differentiation is critical, because treatment varies from support and validation, to talk therapy, to pharmacologic and medical interventions, or a combination of all.

Apart from clinical depression, patients in pain often experience sadness and grief. Sadness is thought to occur after a perceived loss or when life's events deviate from expectations in a negative way.^{62, 63} In that sense, it is completely rational for the person with unexplained or persistent pain to experience sadness and even grief. Grieving for the loss of past and/or current abilities and activities and anticipatory grieving for the loss of future abilities and dreams should be recognized and honored.

Fear and anxiety are part of the emotional experiences of the majority of patients with persistent pain and are associated with the predisposition to develop trigger points (TrPs).⁸⁹ Anxiety and fear are closely related.⁹⁰ Fear is a response to a perceived threat and anxiety is future-projected fear.^{62, 63} Pain itself is a type of danger signal.⁹¹ Patients can fear the effects their pain will have on work performance and expectations, home obligations, hobbies, and future events of all kinds. Kinesiophobia is the specific fear of movement and physical activity, and it is correlated with increased pain and vulnerability. Kinesiophobia can also contribute to fear-avoidant behaviors if it is not addressed.⁹²

State and trait anxiety may also play a role for patients with painful conditions. State anxiety is related to an event, whereas trait anxiety is a lifelong pattern, such as generalized anxiety disorder.⁸⁹ Symptom presentation of both includes feelings of apprehension, tension, being alarmed/on alert, and physical manifestations including increased muscle tension, pain severity, and the constitutional changes associated with the stress response.^{93, 94} Unlike depression, Sorrell et al⁸⁸ found that patients with chronic musculoskeletal pain and anxiety did as well in a multidisciplinary treatment as those

without anxiety.

Anger is an emotional response to an unjust situation or event, which can include the perceived injustice of living with persistent pain.⁹⁵ It can be a way of seeking control over feelings of fear and anxiety. Anger plays an important (modifiable) role in the feedback loop of thoughts, emotions, and behaviors. Healthy expression of anger can be an important part of a biopsychosocial treatment plan because inhibition of anger has been associated with higher pain intensity, increased pain behaviors, and lower activity level.^{96,97}

Shame can also accompany physical pain in some patients. Shame, known as the “master emotion” due to its profound influence on social interaction, is the intensely uncomfortable feeling of not being enough.⁹⁸ Different from guilt (“I did something bad”), shame (“I am bad”) is connected not to actions but to personhood.^{99,100} The difference between “I’m a terrible person” and “I acted rudely” is that the former represents shame and the latter, guilt. Guilt can be useful in that it motivates reparation. Shame, however, is unproductive and is correlated with addiction, violence, and abuse^{99,101,102} and should, therefore, be noted and addressed in any healthcare setting. A common shame verbalization in response to the experience of physical pain is, “I am broken.” Reframing shame statements like this one can be helpful in increasing motivation to change and hope in improvement.

Of course, every person who experiences emotions associated with pain will do so in a personal manner. Some patients are more uncomfortable with some negative emotions than others. Some emotions may even be shame-bound for an individual.^{99,100} A patient who is ashamed of feeling sad may turn to anger, or even rage, to avoid feeling sadness. Conversely, a patient who perceives anger as intolerably uncomfortable or socially inappropriate may display signs of sadness, even when another person would verbalize righteous indignation at the same event. Identifying and understanding emotions related to pain can be an important part of healing, and incorporating emotion regulation considerations within a treatment plan shows promise in improving outcomes with chronically painful conditions.¹⁰³

3.2. Common Behavioral Responses to Pain

Behaviors are thought to be the conscious and unconscious responses to thoughts and feelings.^{35,90,104} Individuals approach medical and health events with personal outlooks, predispositions, and memories. Albert Ellis’ Rational Emotive Behavior Therapy demonstrates the connection between the thoughts and emotions of the (a) activating event and the (b) beliefs and behaviors that lead to (c) consequences.¹⁰⁵ The fear-avoidance behavior paradigm posits that thoughts and feelings about pain can lead to maladaptive behaviors and reinforce negative consequences. Pain perceived as nonthreatening may not inhibit engagement in daily activities, whereas thoughts of pain as threatening and harmful often lead to pain-related fear and safety-seeking behaviors. This model has been used to explain why some patients with acute low back pain develop chronic low back pain with associated disability.⁹⁰ The fear-avoidance model of musculoskeletal pain has evolved since

its inception⁹² to include pain severity, pain catastrophizing, attention to pain, escape/avoidance behavior, disability, disuse, and vulnerabilities.⁹⁰

Similarly, patients' behaviors around exercise adherence can be linked to past experiences. Blaming or stigmatizing patients who appear reticent to engage in "active" therapy interventions is unwarranted and ineffective. Humans learn through experience. Reduction in pain-related anxiety predicts improvement in function and adoption of active behaviors. In their study of patients with central sensitization, Wijma and colleagues¹⁰⁶ presented three groupings of behavioral responses of patients with persistent pain: (1) healthy behaviors as defined by the pain experience with no or little fear, with constructive use of techniques (pain acceptance), (2) avoidant behaviors, with greater fear and nonconstructive techniques, and (3) persistence behaviors, defined as pushing through activities to completion despite the perception that the activity is too hard. The second and third groups display overactivity and underactivity responses, respectively.

Support and accountability, or lack thereof, can also impact behavioral responses to painful conditions. Just like the temporary use of a brace can be helpful in healing after an ankle sprain, so too can social bracing improve adherence to, and positive outcomes with, treatment strategies (see below on the therapeutic alliance). In contrast, patients without social support and who feel like no one cares if they get better may become overwhelmed and demotivated to take steps to improve their situation. Motivation and readiness-to-change are paramount to behavioral outcomes and are not static.^{106, 107} The interrelated components of many psychological and sociological theories within a single pain experience is often quite evident.

3.3. The Experience of Living With Pain

Individuals living with pain (especially when persistent and/or unexplainable) face daily hardships that are often compounded by interactions within the healthcare arena. Practicing within the boundaries of the biomedical model, stigmatization, discrimination, and disrespect of the individual with persistent pain are all disturbingly common. Frequently considered as "baggage" by clinicians, the psychosocial factors that accompany the patient are as significant as the physical ones, and the patient can often perceive the clinician's discomfort with those concerns.

Fragmented treatment episodes are common; chaotic and haphazard treatment experiences are the norm. Sometimes, desperate pleas for help and explanations can elicit labels like "high maintenance," "psych overlay," and "problem patient." These labels, and even the more modern, medicalized words, such as "catastrophizing," "fear-avoidant behaviors," and "somatization," can further alienate the patient and worsen feelings of shame. Intake forms with these words emblazoned on the top can trigger emotional response that may be ineffective in establishing a therapeutic alliance or hope in a new episode of care.

The complexity of relatively nonmodifiable psychosocial variables (eg, the individual's personality, the individual's diagnosed disordered personality),¹⁰⁶ and potentially

modifiable variables (eg, access to healthcare, employment responsibilities, financial stressors, life stressors), are interactive. Negative effects on life roles are challenging and include role strain (inconsistencies within a role), role conflict (incompatible requirements between roles), role ambiguity (lack of clarity about expected behavior), and role insufficiency (the inability to fulfill role expectations, obligations, or goals).¹⁰⁸ These stresses compound and can increase pain when perceived task and role demands exceed perceived coping capabilities and abilities.⁹⁴ Conversely, underload stress may also occur—feeling unable to make full use of talents and skills because of the limiting force persistent pain and the accompanying loss of time and energy its management requires.

Many patients who feel distressed by, or even incapable of, tolerating a painful condition accrue a laundry list of diagnoses, both mental and physical. The psychology of diagnosis is extremely personal and official medical labels may be helpful or ineffective in a process of recovery, depending on the patient. Despite historical norms of many varied diagnoses under a general category of somatoform disorders, or the newer trend to lump any psychosocial concern into a catch-all of “Somatic Symptom Disorder,” adjustment disorder remains the most appropriate, accurate, and acceptable diagnosis for people who are hyperconcerned about their pain.¹⁰⁹

4. CLINICIANS WHO TREAT PATIENTS LIVING WITH PAIN

4.1. Current Challenges to Practicing Within a Biopsychosocial Model

Many clinicians feel a lack of preparedness to address social and behavioral concerns, and rightly so, because more often than not, neither their entry-level education nor their postprofessional development has equipped them to do so in any concrete way.⁷ Others may feel that by asking questions on an intake form about living situations and a question or two about mood, that they are already practicing from as close to a biopsychosocial vantage point as they are willing to go. Some may not want to engage in a more holistic approach after rigorous biomedically specific training, and their practice reflects that.^{110–112} Focusing on anatomic concerns and aggressively controlling the human interaction to minimize the patient’s thoughts, emotions, and behaviors certainly can be “simpler.” The practitioner may feel truly vulnerable and ill-prepared for his or her own emotional responses to a patient’s expression of sorrow and suffering. External variables provide even more barriers—healthcare plans, productivity standards, lack of access to care, attempts to “streamline” care—all have the potential to weaken or limit clinicians’ abilities to practice from a biopsychosocial perspective.

The biopsychosocially conscious practitioner acknowledges and embraces what can appear to be competing approaches to providing comprehensive care.¹¹³ There is the linear structural causality of the biomedical piece (eg, the presence of myofascial TrPs) and the complexity and recursive aspects of the psychosocial pieces (eg, fear and anxiety, the lack of family support, “failed” prior efforts). The biopsychosocially aware practitioner links the two and designs and manages a treatment plan to support the trajectory of healing and function with the awareness of the often “three steps forward, two steps back” course of

care.^{4,106} It is often a fine line to tread. The clinician must have the knowledge and working framework of how, and how far, to delve into the patient's psychosocial experiences and the skills to provide an integrated treatment, to know which patients would benefit from referral for psychological or other specialized care, and when, how, and to whom to refer.¹¹⁴ The clinician is obligated to know his or her own professional limitations and boundaries, and to refer appropriately.

Staying in the biomedical box is no longer an option, because there is ample evidence that clinicians' views are subsumed by patients, and that practicing from a purely biomedical model "teaches" fear-avoidant behaviors.^{7,115,116} Given that patients likely come with strong biomedical views based on prior experiences, it is imperative that practitioners understand that their continued focus on that paradigm "is likely to result in poor compliance with evidence-based treatment guidelines, less treatment adherence, and poorer treatment outcomes" especially in terms of functional recovery.⁷

4.2. Clinician Self-Awareness

Poor clinician self-awareness lends itself to poor patient relationships. Behaving differently toward the person with a persistent pain problem may be secondary to the clinician's own prejudice, fear, or indifference.¹¹⁷ The need to depersonalize, and efforts to evade or circumvent (consciously or not) patients' feelings by interrupting, shifting topics, or disallowing opportunities for broaching sensitive subjects may be rooted in the clinicians' need to distance themselves because of feeling powerless or may simply be a symptom of compassion fatigue.^{117,118}

Improving self-awareness is a process and must be practiced. In her text aptly entitled, "Patient Practitioner Interaction: An Experiential Manual for Developing the Art of Health Care," Carol Davis addresses the underlying values practitioners may have that detract from a therapeutic interaction. She includes personal assessment tools for the reader to consider his or her own values to allow for the exploration of personal biases that may affect patient care. Nijs et al⁷ present an approach toward effective and evidence-based care for clinicians treating patients with persistent pain. The clinician's first step is self-reflection. Just as patients must acknowledge and address their illness beliefs, clinicians must also address their own perceptions of biomedical versus biopsychosocial interventions. Because evidence demonstrates that clinicians' beliefs about musculoskeletal pain are predictive of treatment recommendations,¹¹⁹ and that previous treatment by a biomedically oriented clinician is a risk factor for patients with low back pain on long-term leave from work,¹²⁰ clinicians must consider their own ineffective beliefs.⁷ After self-assessment and adjustments in attitudes and beliefs regarding persistent pain, the clinician can better consider the patient's illness beliefs.⁷ Ongoing self-audit is necessary because professional performance is never the same moment to moment.¹²¹ Constant vigilance is a fundamental requirement for professionals who require high reliability in the face of unexpected events.¹²¹ For clinicians who treat patients in pain within a biopsychosocial framework, this professional self-awareness must occur in an emotional realm as well as in the domains of skills and knowledge.

Countertransference

Countertransference refers to the reactions or feelings—positive or negative—that occur when the practitioner unconsciously transfers his or her own needs, desires, fears, or frustrations onto the patient. Engaging in regular self-reflection is needed with all patient interactions, not just the negative ones. The practitioner should consider why some interactions with patients are “good” and others “irritating.” Instead of using any insight, or therapeutically helpful reactions, the practitioner may be using responses to label or find fault with the patient. Similarly, stigma and attribution occur in context.¹²² Factors that intensify stigma include lower socioeconomic status, living in rural areas, race, gender, and preexisting ideas about a group.⁸² As such, stigma and the associated blame ascribed to individuals with pain must also be simultaneously considered with stigma from other “labels.”¹²³ Clinicians can take Internet-based tests to determine their own implicit bias against certain groups of people based on race, age, ability, gender, sexual orientation, and body type. Knowing one’s own areas of bias is key to improving and practicing consistent care for all patients. The impact is cumulative or even exponential. Clinicians need to question their own perceptions regarding the attribution or stigma they may be applying to their patients with myofascial pain syndrome.

Discomfort With Negative Emotions

Clinicians who treat patients in pain must practice allowing patients to express negative emotions and to have complex, and sometimes paradoxical, thoughts and feelings about their pain experience.^{113, 114} According to Jung, “only paradox . . . comes anywhere near to comprehending the fullness of life.”¹²⁴ Painful emotions often accompany physical pain. Unfortunately, in attempts to improve a patient’s outlook, clinicians can dismiss and invalidate the expression of difficult emotions from patients (“Oh, don’t feel bad, you’ll get better!”). Clinicians may even be unaware of their own discomfort with certain emotions. For example, a clinician who values strength and associates the expression of sadness or vulnerability with weakness may implicitly or explicitly require that the patient withhold his or her expression of these feelings, thus jeopardizing the therapeutic alliance and reducing patient motivation to actively engage in treatment. Conversely, a patient’s negative reactions, well managed, can actually be used to strengthen the patient–clinician relationship.¹²⁵

4.3. Psychosocial Strategies for Clinical Practice

Focusing on the Sphere of Influence

The challenge for many clinicians is where to start and how to begin this process of managing all of the varied biopsychosocial aspects that may emerge from the initial evaluation of a patient in pain. A variation of Stephen Covey’s concept of “circle of concern/circle of influence” can be helpful for organizing and managing the various aspects

of patients with complex presentations. Covey introduces this concept in his book, “7 Habits of Highly Effective People.”¹²⁶ Although it is intended for the application for proactive personal change, a similar approach can be advantageous in helping clinicians develop a conceptual biopsychosocial framework.

In this context, the concept can be depicted with two overlaid objects. The larger, outer one is the Red Zone and includes those aspects of the patient’s experience on which the clinician has no direct impact. The smaller, inner area, the green zone, includes those aspects upon which treatment has direct influence. Just as Covey posits that time and energy focused on the inner circle allows for personal growth and development, a clinician should focus time and energy on the aspects of patient’s problems that can be affected with available treatment strategies to best effect change across the biopsychosocial continuum. For example, treating myofascial TrPs and postural issues, addressing cognitive distortions and erroneous thoughts, providing strategies for sleep positions and sleep hygiene, and addressing kinesiophobia and fear-avoidance behaviors could all be put into the inner green zone. Focusing interventions on these items enhances the patient’s self-efficacy and HLOC. The outer realm includes those things that are outside of the clinician’s ability to directly effect change, such as the patient’s job situation, grief over an unhappy marriage, and the fact that the patient has had multiple back surgeries. The clinician can and should validate these concerns, empathize, and refer to other professionals as appropriate. Although no concern should be ignored or minimized, attention is best given to those things that can be influenced.

Coupled with the International Classification of Functioning, Disability, and Health model that considers the patient from structure and function (diseases/disorders and impairments), activity (limitations), and participation (restrictions) within the contextual factors of the environment and on a personal level, the clinician can develop a plan of care that has at its forefront the patient’s goals, with pathways that include and link the biopsychosocial aspects of care.¹²⁷

Developing an Effective Therapeutic Alliance

The evolution from the paternalistic model of decision-making to the shared decision-making model, and the more appropriately and comprehensively named, patient-centered care model, depends on facilitated therapeutic communication and the clinician’s abilities to establish a therapeutic alliance with the patient.¹²⁸ Patient-centered care involves “taking into account the patient’s desire for information and for sharing decision making and responding appropriately.”¹¹³ Founded on the clinician’s ability to demonstrate the facilitative behaviors of acceptance (“I care”), genuineness (self-awareness), and empathy (an impartial, but caring understanding of the client’s feelings and experiences),^{46, 129} it requires authenticity from the provider. Development and demonstration depend on the clinician and is clinician-specific. Clinicians with different personalities and communication styles use different approaches to establish an authentic client-centered atmosphere. Effective helpers must have a clear sense of self and their own personal

boundaries. Their purpose is to facilitate and assist rather than control, and to be process-oriented and committed to working out solutions, rather than working toward preconceived goals or notions.^{117, 130}

Boundaries

Boundaries are extremely important for the maintenance of an effective therapeutic alliance between clinician and patient. It is up to the clinician to define his or her limits regarding things like communication, scheduling of appointments, and clinical interaction norms. For example, some clinicians find the use of e-mail or texting between appointments helpful, whereas others find this kind of communication oppressive. One clinician may not mind a patient's expressive use of curse words within the therapeutic interaction, whereas another may be offended. Oftentimes, clinicians learn their limits through trial and error. Resentment or social disgust felt by the clinician is a good signal that a boundary has been breached. Clinicians must stay mindful of internal cues such as resentment, dread, blame, or judgment around any particular patient. If these emotions arise, curious exploration will often elucidate a triggering event. After this event has been identified, communication with the patient to reaffirm the limits of the therapeutic relationship may or may not be necessary. When clinicians fail to set and honor their own personal boundaries with a particular patient or client, the therapeutic alliance will be jeopardized. When clinicians fail to set any clinical boundaries at all, professional burnout is likely.¹³¹ Because boundaries are extremely personal, each clinician must practice self-awareness to establish and reestablish them, because what the clinician may be able to offer can change along with his or her own life circumstances.

Unconditional Positive Regard

Carl Rogers developed the concept of unconditional positive regard as part of his humanist client-centered therapy model.^{45, 46} Adapted for use in modern healthcare of many varieties,⁴⁷ unconditional positive regard may be understood as separating patients from the behaviors they demonstrate, or put colloquially, always “giving the patient the benefit of the doubt.” As described above, patients with painful conditions can exhibit frustration, anger, distrust, and other emotions and behaviors that can be challenging in a fast-paced healthcare setting. Verbalizing that these emotional states and ineffective actions are self-protective and, given the circumstances of the patient's situation, completely understandable, can honor the hope of change and improvement. Labeling an individual as a “problem patient” or worse, negatively affects all aspects of the therapeutic relationship. Unconditional positive regard is a powerful antidote against the shame that many people feel when their emotional responses to pain cause further suffering.

Validation

Validation is a key component in establishing the trust that allows for the easy flow of

information between patient and clinician. Patients with low back pain have been shown to respond negatively to the invalidation of pain by primary care physicians.⁷⁰ One strategy for using validation to respond to patients' verbalized pain reports, thoughts, or emotions may be summed up in two words: "Of course . . ." For example, a patient may verbalize frustration at not being able to lift his toddler due to shoulder pain. The reply, "Of course, you are frustrated by that. You love your daughter and want to be able to soothe her, hold her, and when needed, keep her safe" can be extremely effective in making the patient feel heard and understood. In contrast, the reply, "Don't worry about that—she's a big girl now and you'll be able to lift her again after this treatment" may be perceived as dismissive and pejorative, rather than optimistic and motivational, as intended.

The validation of a patient's feelings, thoughts, and past actions have been seen, clinically, to be invaluable in managing psychosocial distress related to physical pain. Verbalizing understanding that a patient is doing the best he or she can, given the circumstances, can be especially effective for patients who demonstrate a Powerful Others HLOC to increase their willingness to engage in effective pain behaviors. Lastly, recognizing the pervasive use of hyperbolic language in some cultures, clinicians may find that validating the feeling beneath an exaggerated statement more helpful than encouraging the patient to immediately reframe it. A statement like "I just can't take this pain anymore. It's killing me!" could be validated by saying, "It sounds like your pain is really intense and hard to even tolerate." Some patients who mark their pain as a 10/10 on a form are attempting to legitimize their suffering and may just need to feel heard and understood.

Self-Care

Self-care transcends basic hygiene and life-sustaining activities to include tending to the enjoyable aspects of an individual's personal life including creativity, spirituality, pleasure, and recreation, among others. Self-care outside of the clinic is important for both the patient and the clinician. Patient self-care may help mitigate physiologic distress. And because it is an opposing action to self-loathing and helplessness, it can also help reduce feelings of shame, while improving autonomy and strengthening an internal LOC. Clinicians may even instruct patients in basic self-care as part of a home exercise prescription. Tailoring specific self-care strategies to the needs, preferences, and values of the patient are more likely to garner adherence. One starting point for helping a patient craft a self-care plan is to instruct him or her to engage the five senses. Pleasant sensations can help soothe the autonomic nervous system and lift one's mood. Another way to consider self-care is to adopt strategies to improve physical wellness (eg, exercise or stretching), mental wellness (eg, meditation), emotional wellness (eg, practicing gratitude), spiritual wellness (eg, prayer), and social wellness (eg, volunteering). These strategies should align with the individual's values and vary in the amount and type of resource investment required (eg, time, energy, money, social support). For patients who prefer simple mantras, self-care can be described as anything that makes them feel "happy, safe, and good."

Self-care for the clinician is equally important and can improve the ability to empathize

with and validate the negative emotions of patients. Because empathy has been shown to reduce with patient exposure,¹³² clinicians must be persistent in their efforts to maintain the ability to do the exhausting emotional work of patient care.^{118,133} Finally, clinicians who establish healthy boundaries, demonstrate unconditional positive regard, validate emotions, and practice effective self-care model the kinds of healthy behaviors that patients may use to improve distress tolerance, accept pain, and adopt values-based coping strategies.

First Impressions

The importance of the initial evaluation cannot be overstated. Developing the therapeutic alliance is the obligation of the clinician. Using a systematic approach to patient interactions such as the one described by Lyles and colleagues,¹³⁴ and introduced by Smith,¹³⁵ can be helpful. A 5-step approach to initial encounters with patients begins with (1) setting the stage—meeting the patient and introductions and is followed by (2) setting the agenda—letting the patient know what is going to happen, including the amount of time of that visit. These seemingly obvious steps take only a minute or two, but are often overlooked. Step 3 is nonfocused interviewing, where the patient has an opportunity to respond to an open-ended beginning question. Considering that patients are generally interrupted within the first 12 to 18 seconds of speaking during a medical appointment,^{136,137} being provided an opportunity to speak might be a novel, and hopefully positive, experience. Active and focused listening during the nonfocused interview is key. Much can be learned during this time about patients' pain journeys and their prior episodes of care. Aspects of their personality and values can also be noted as well as their thoughts, feelings, and beliefs about their pain experiences. All of these impact the episode of care. Threats and vulnerability may be felt by the patient with regard to the ability to be autonomous, to fulfill roles, to retain life and work goals, and to economic well-being, to name but a few.¹³⁸ A comprehensive view of quality of life is subjective, and treatment must be founded on the patient's definition of quality and his or her goals.¹³⁹ Step 4 is focused interviewing, during which the clinician asks specific questions to guide the evaluation. And finally Step 5 is a clear transition to the physical examination and assessment. Simple additions to the initial evaluation, such as letting the patient know how much time he or she will have with the clinician and how long the appointment will last, enhance a sense of security and mutual respect.

Clinician as Educator

In addition to the goal of reducing and managing pain, another goal of any episode of care based on biopsychosocial principles should include carefully expanding patients' knowledge of their own body and the pain they experience—including the role of thoughts, emotions, and behaviors. The literature has yet to identify a single accepted term for this education, with therapeutic/pain neuroscience education (TNE and PNE) being most commonly cited. Moseley and Butler introduced the term "curriculum" to more fully capture the

comprehensive education that occurs in biopsychosocial management and includes the learner, the deliverer, the message, and the context.⁹¹ The clinician—the deliverer of the information—must be competent to do so. Similar to the practitioners' abilities to demonstrate intervention-based competence, abilities to demonstrate education-based competence is equally critical.^{70,91}

Education along with CBT has been shown to be effective, but is not always well received by patients.¹⁴⁰ How and when the information is delivered is critical. Earnest efforts in relaying the concepts of operant conditioning or cognitive distortions can trigger a patient's all-too-familiar feelings of shame and stigma, where they only hear that they are causing their own pain. Education is most effectively initiated through lessons on physiology³⁷ with an emphasis on first validating the patient's experiences and decisions up to this point in time. Prior to incorporating education, it is vital that the clinician's and patient's attitudes and beliefs must be aligned.¹⁴¹ Basing initial education on the consequences model, which distinguishes itself by its labeling of psychosocial distress in terms of consequences rather than as causes of physical symptoms, as Zonneveld and colleagues recommend, could be significant in a patient's receptiveness to embrace interventions that include aspects other than the expected physical ones like manual therapy and exercise. As such, clinicians need a basic understanding of a variety of cognitive and behavioral interventions, as well as the ability to incorporate at least a few with some level of comfort and expertise. These strategies are as important as knowledge and resources to refer out when appropriate. Learning how to teach, motivate, and support is a key component of success within a biopsychosocial healthcare model.

Intentional and Therapeutic Communication

Throughout all aspects of an episode of care, and especially during education, clinicians should choose their words carefully and with a goal of reducing fear and anxiety and improving the efficacy of therapeutic communication. Words matter. Most clinicians use metaphors to explain complex medical realities. These explanations can either increase the sense of danger for a patient or quell it.^{91,142} Unfortunately, medical terms and the words clinicians use to describe and explain their patient's pain can add to misconceptions and confusion for the patient. Patients are constantly crafting stories about their pain and what is happening to them.⁹¹ The patient who describes his pain as feeling "like I'm being stabbed in the back" not only needs relief from pain, but also needs the knife taken out of his pain story. Medical terms such as "degeneration," "herniation," and "pinched" may trigger fear and danger in a patient depending on his or her previous exposure to such terms. As noted above, even historical terms rooted in psychology and cited in this chapter (eg, cognitive distortions, catastrophizing) can sound judgmental and harsh to a patient. When in doubt, choosing the most accurate and least alarming words when describing a patient's condition ("crowded nerve" instead of "pinched nerve") may be the most effective way in reducing pain and improving functional outcomes related to pain behaviors.

Effective clinical education delivers a message that describes reality, encourages

proactivity, and minimizes the patient's anxiety.^{71,91,142} The wise clinician modifies language in response to the signs of increased distress during educational explanations. Because a patient's pain story is dynamic and ever evolving, the clinician's role is to help the former develop adaptive beliefs about the relationships between pain, movement, anxiety, and protective behaviors.⁷¹ Individually tailored education programs must be constantly assessed and reassessed on the basis of patient response.

Another important communication strategy to employ is patient-first language when considering patients with persistent pain. Language that identifies patients by pathology or painful body part typifies the detached biomedical paradigm. Referring to an individual as "a fibromyalgia patient," "a chronic pain patient," or "a knee patient" is a counter to person-centered care and can reduce the efficacy of the therapeutic alliance. Clinicians should monitor the language they use to label patients, for labels prioritize the disease over the individual.¹⁴³

5. CLINICAL REASONING

Clinical reasoning is grounded in human perception⁷¹ and must address the complexity of the human experience. A biopsychosocial model should not be used as a reason to ignore biomedical matters. Clinical reasoning must include the reconceptualization of the clinician's and patient's attitudes and beliefs to narrow the gap and allow for alignment of beliefs between the two prior to incorporating education.⁷ Several models exist to conceptualize both clinical reasoning processes and development and include the whole patient. Collier et al¹⁴⁴ presented a new model of clinical reasoning development demonstrating the trajectory from novice to expert clinician across the three areas of logic (diagnostic, contextual, and management thinking), performance (skill, time, and efficiency), and presence (rapport, confidence, therapist identity). This model supports the development of the interrelated clinical reasoning aspects of thinking, doing, and being as part of the biopsychosocial evaluation.

Edwards et al separated clinical reasoning into two major clinical strategies: diagnosis and management. They discuss the aspects of diagnostic reasoning strategy, narrative (inductive) reasoning, that is most focused on the patient's experience and beliefs, contextualized by social and environmental factors and combined with diagnostic (deductive) reasoning around physical impairments, symptoms, and physiologic mechanisms.¹⁴⁵ The management strategy is made up of interactive reasoning, collaborative reasoning, reasoning about procedures, reasoning about teaching, predictive reasoning, and ethical reasoning.

Biopsychosocial assessments incorporate somatic (bottom up) and psychosocial (top down) factors.^{89,106} Speckens and vanRood¹⁴⁶ presented the SCEBS model for treating patients with unexplained physical symptoms. On the basis of CBT, the model addressed the following five factors for consideration: S: somatic and medical, C: cognitive (pain perceptions and beliefs), E: emotional (anxiety, fear of movement, anger, depressive feeling, stress), B: behavioral (operant conditioning, focusing on effective behaviors), and S: social.

Wijma and colleagues added two factors to this model in 2016—identifying the type of pain (nociceptive, neuropathic, or nonneuropathic central sensitization) and motivation for change (Type of Pain + SCEBS model + Motivation).

Within the realm of clinical reasoning and persistent pain, stereotype-based bias must be addressed. Burgess and colleagues¹⁴⁷ identified two sets of cognitive processes that contribute to clinical judgment including evidence-based processes that are situation-specific, conscious, logical, effortful, and intuitive that are less situation-bound, almost automatic, affect-laden, and include clinicians' explicit and implicit biases. Intuition can be an excellent tool but is best utilized by the expert clinician because effective intuition is developed with experience and repeated exposure to large numbers of patients.¹⁴⁸ Biases, however, often hidden or minimized by colleagues, impact decision-making about pain¹⁴⁹ and can lead to negative outcomes. Bias is often perceptible to patients and serves as a barrier to quality care, increasing vulnerability to alienation and shame.¹⁵⁰

The Use of Outcome Measures

Accurate evaluation of the biopsychosocial elements of a patient's pain presentation is important for any medical encounter. The use of validated surveys and questionnaires to garner more information to guide treatment and assess outcomes is helpful and recommended. One consideration, apart from the appropriate selection of these tools, is how a form appears from the patient's perspective when given with no context, sometimes even prior to meeting a clinician. The Pain Catastrophizing Scale,¹⁵¹ although useful, is one example of a questionnaire with a title that may trigger a patient's real or perceived discrimination from the "powerful other" healthcare provider and may, therefore, exacerbate the internalized feelings of being burdensome, incapacitated, or powerless. It reduces the likelihood that the patient will follow through with suggested options for emotional or medical support, resulting in poorer long-term psychological and physical health problems for people with persistent pain.¹⁵² Omitting the title(s) from these questionnaires can help avoid these challenges.¹⁰⁶

5.1. Multimodal Treatment Strategies

Interventions that target single domains—physical only, psychological only—are less effective than multimodal ones.^{153,154} Mind and body practices are a large and diverse group of techniques (National Center for Complementary and Alternative Medicine for the NIH). Combining manual therapy and exercise with PNE is more effective than when education is presented alone.^{155,156} Integrating education pieces with active, movement-based strategies can be beneficial because they can reinforce each other; however, inconsistent messages between the two may adversely impact movement.³⁷ "Pain neuroscience education (PNE) alters the threat value of movement, while subsequent movement confirms or refutes this new belief while providing repeated sensory inputs required for creating enduring shifts in the autonomic movement and stress response."³⁷ In

their review, Puentedura and Flynn¹⁵⁶ stated, “providing manual therapy within a PNE context can be seen as meeting or perhaps enhancing patient expectations, and also refreshing or sharpening body schema maps within the brain. Ideally, all of this should lead to better outcomes in patients”.

Practitioner education, training, and mentoring for how to combine and deliver optimal physical and psychosocial interventions is needed and is paramount to the success of delivering integrated care models.^{113,157,158} In a systematic review of the efficacy of PNE on musculoskeletal pain, Louw and colleagues¹⁵⁵ identified the benefits of reduced pain, improved patient knowledge of pain, improved function, lower disability, reduced impact of psychosocial factors, enhanced movement, and less healthcare utilization. Models of intervention varied from Physical Therapy-delivered one-on-one sessions to group sessions to patient-read options. There were no instances of the treatment group faring worse than the control group, which supports a risk-benefit ratio in favor of integrated models.¹⁵⁵ CBT-based techniques include distraction, imagery, motivational self-talk, relaxation training, biofeedback, the development of coping strategies, goal setting, and changing maladaptive beliefs about pain. CBT interventions are based on the view that an individual’s beliefs, evaluation, and interpretation about his or her health condition, in addition to pain, disability, and coping abilities, impact the degree of both physical and emotional disability of the pain condition.

An understandable challenge to assessing the effectiveness of integrated interventions is the requirement that they be standardized, mandatory, and prescriptive, with home practice “dosage” (ie, the practice of skills like progressive muscle relaxation or distraction techniques) also standardized. Although necessary for measuring outcomes, it is antithetical to the biopsychosocial focus of individually tailored plans of care.

5.2. The Role of Referral

Referral is an important tool for any musculoskeletal clinician who practices from a biopsychosocial perspective. Just like any clinical strategy, referral can be both under- and overutilized. Many orthopedic clinicians are reticent to implement any psychosocial strategies for fear of overstepping professional margins. But evidence supports musculoskeletal clinician-delivered psychological interventions within the practice context.^{155,157–161} Of course, swift referral is the most appropriate action for patients with high levels of psychological or emotional distress that feel unmanageable for either patient or clinician or that might result in harm to the patient or others. And patients with diagnosed psychological disorders should be monitored and managed by a mental health professional or team. Suggesting referral at the patient’s first mention of psychological distress, however, can damage the therapeutic alliance and deter further divulgence of information related to a patient’s experience that could impact the plan of care. Referral simply to reduce the risk of clinician liability does not necessarily produce the most effective patient outcomes. Clinically, it has been seen that effective referrals occur after the establishment of a sound therapeutic alliance and after the patient has acknowledged an

interest in, and willingness toward, further treatment as presented by the clinician.

6. CONCLUSION

Clearly, the topic of psychosocial considerations for treating patients with painful conditions is too broad for a single chapter or book. This chapter merely highlights a few potentially helpful concepts and strategies. Because no psychosocial treatment intervention will work for every patient, clinical reasoning must be applied to each individual patient case to select strategies, assess outcomes, and modify the plan of care as needed. The biopsychosocially oriented clinician fosters seven key psychosocial aspects in daily practice: developing self-awareness as a result of ongoing self-audits, creating trust and minimizing countertransference, cultivating empathic curiosity, recognizing bias and attribution, educating emotions and tolerating uncertainty, using informed intuition, and effectively communicating the clinical plan and evidence.⁴ Increasing patients' self-regulatory strengths should underpin all treatment interventions. For patients living with persistent pain, "It is exceedingly difficult to maintain hope and optimism if one is plagued by self-doubt in one's ability to influence events and convinced of the futility of effort."¹⁶²

Providing an environment of support and accountability that fosters strengthening self-efficacy and healthy behaviors, and providing opportunities to redirect attention toward education and empowerment can all help improve pain and functional outcomes. Activities and beliefs are mutually positively reinforcing. Whether using physical, cognitive, motivational, or emotional strategies to augment the treatment of myofascial pain and dysfunction, clinicians should strive to maintain a positive therapeutic alliance, stay in the circle of influence, and increase patients' self-regulatory strength to improve progress toward functional goals and overall quality of life.

Trapezius Muscle

“Stress Headache Producer”

Michelle Finnegan and César Fernández de las Peñas

1. INTRODUCTION

The trapezius muscle is one of the main muscles of the cervical spine, consisting of three portions: upper, middle, and lower. It is mainly involved in movements of the neck and shoulder region (upper portion), although the middle and lower portions are also involved in the thoracic spine. The trapezius muscle is probably the muscle most often affected by trigger points (TrPs) seen in common clinical practice. The upper portion of the muscle refers pain unilaterally upward along the posterolateral aspect of the neck and extends to the temple and the back of the orbit, mimicking tension-type headache; the middle portion of the muscle refers pain to the shoulder, and the lower portion of the muscle usually refers pain to the neck or suprascapular region, contributing to mechanical neck pain. Symptoms reported by patients may include reports of a “stiff neck,” headache, “shivers running up and down my spine,” and neck and shoulder pain. Activation and perpetuation of TrPs in the trapezius muscle usually result from sudden trauma, whiplash from a motor vehicle accident, a fall, or improper work station setup. Differential diagnosis should include tension type and migrainous headache, temporomandibular joint dysfunction, intervertebral joint dysfunction, occipital neuralgia, and interscapular pain as well as subacromial pain syndrome (shoulder impingement). Corrective actions include postural and ergonomic education, proper sleep positioning, avoiding activities that overload the trapezius muscle, self-pressure release of TrPs, and self-stretch exercises.

2. ANATOMIC CONSIDERATIONS

The upper, middle, and lower portions of the trapezius muscle have different fiber directions and often have different functions. In this chapter, the three parts are frequently identified as if they were three different muscles. Clinically, the boundary between any two parts is frequently indistinguishable by palpation and is defined only by the location of the

attachment of fibers in relation to the spinous processes, scapular spine, acromion, and clavicle. When the right and left trapezius muscles are viewed together from the rear, they appear to have a large diamond shape. Together, the fibers of both upper trapezii muscles are shaped like a coat hanger.

Upper Trapezius Fibers

The upper (superior) fibers arise from the medial third of the superior nuchal line. In the midline, they arise from the ligamentum nuchae (Figure 6-1). The fibers converge laterally and forward and attach to the posterior border of the lateral third of the clavicle (Figure 6-2).¹

Figure 6-1. Attachments of the right and left trapezius muscles, rear view. The midline trapezius attachments extend from the occiput to the T12 spinous process.

Figure 6-2. Attachments of the right trapezius muscle, side view. The longest, most vertical fibers (ones that cross the greatest number of joints) are the fibers most likely to develop

trigger points.

A careful anatomic analysis of the direction of fibers in the upper trapezius muscle revealed that, contrary to the impression given by most authors on the subject, none of the superior (upper) trapezius fibers are in a position to exert a direct upward force on the clavicle or the scapula.² A few thin fibers that have a vertical orientation from the superior nuchal line swing around the neck and pass almost horizontally, only slightly downward, before attaching to the clavicle.

Johnson et al² reported the transversely oriented fascicles in this superior part of the trapezius muscle as arising from the lower half of the ligamentum nuchae and inserting into the lateral third of the clavicle. The larger fascicles of upper trapezius fibers run nearly horizontal (at an elevation of $>20^\circ$) and are in a position to draw the lateral end of the clavicle medially and upward by swinging it around its attachment at the sternoclavicular joint. Through this rotation of the clavicle about the sternoclavicular joint, these fibers of the upper trapezius can raise the clavicle and (indirectly through the acromioclavicular joint) the scapula.

The greater occipital nerve can be compressed by the vertical fibers of the upper trapezius muscle.³⁻⁵ The greater occipital nerve is the medial branch of the dorsal primary division of the second cervical nerve and supplies sensory branches to the scalp over the vertex. This cervical nerve emerges below the posterior arch of the atlas above the lamina of the axis, and then it curves around the lower border of the oblique capitis inferior muscle, which it crosses before penetrating the semispinalis capitis and trapezius muscles near their attachments to the occipital bone.³

Middle Trapezius Fibers

According to Simons et al,⁶ the middle portion of the trapezius muscle originates from the spinous processes and supraspinous ligaments from C7 to T3 vertebrae and inserts to the medial margin of the acromion and superior lip of the spine of the scapula (Figure 6-1).¹ Johnson et al² considered the middle part of the trapezius muscle those fascicles arising from C7 and T1, with the C7 fascicle attaching to the acromion and the T1 fascicle attaching to the scapular spine.

Lower Trapezius Fibers

According to Simons et al,⁶ fibers from this fan-shaped part of the trapezius muscle originate in the spinous processes and supraspinous ligaments from T4 to T12 vertebrae, pass into an aponeurosis gliding over a smooth triangular surface at the medial end of the scapular spine, and is attach to a tubercle at its lateral apex (Figure 6-1).¹ Johnson et al² considered the lower part of the trapezius muscle those fascicles arising from spinous processes starting at T2. The fascicles from T2 to T5 converge to a common aponeurotic tendon that attach on the scapula at the deltoid tubercle. When present, fascicles from T6 to of the scapula T10 insert into the medial border of the deltoid tubercle. Lower fascicles,

when present, insert into the lower edge of the deltoid muscle.

2.1. Innervation and Vascularization

The trapezius muscle is innervated by the spinal (external) portion of the accessory nerve (cranial nerve XI). This nerve originates in the spinal nucleus of the spinal cord of the upper five⁷ or six^{8,9} cervical segments. The fibers from the cervical segments merge to form a trunk. The spinal root enters the posterior fossa of the cranium through the foramen magnum. Here the spinal root joins briefly with the cranial (internal) root to form a single nerve trunk (accessory nerve). The accessory nerve exits the jugular foramen, heading toward the retrostyloid space.⁸ From here the nerve divides into the cranial and spinal portions of the accessory nerve. The spinal accessory nerve typically passes laterally to the internal jugular vein.^{10–12} Although less frequent, the nerve can also pass medial,¹² through,^{12,13} or split around¹² the internal jugular vein. The nerve then descends in an oblique manner, staying medial to the styloid process and stylohyoid and digastric muscles.⁷ From here the nerve more commonly travels through the two heads of the sternocleidomastoid muscle,⁸ but could also travel between the muscle's two heads.¹⁴ In this region, the nerve forms an anastomosis with fibers from C2 to C4.^{8,15–17} Then the nerve travels obliquely through the posterior triangle, toward the deep cervical fascia and the trapezius muscle, staying in a fat layer between the trapezius and levator scapulae muscles.^{7,14}

It is thought that the C2-C4 connections carry sensory (mostly proprioceptive) information. Contrary to this thought, electromyographic^{18,19} and histochemical¹⁸ data show that the nerves have both sensory and motor functions, thereby contributing to some degree of contraction to the three portions of the trapezius muscle. However, the motor input from C2 to C4 nerves is not consistently present or is irregularly innervated to the three parts of the muscle when it is present.¹⁹

Although lesions to the spinal accessory nerve are rare, iatrogenic injury contributes to most of the insults to the spinal accessory nerve. Injury often occurs during radical neck dissection, modified radical neck dissection, or functional neck dissection for removal of cervical lymph node metastases from head and neck cancer.^{16,20–23}

The vascularization of the upper portion of the trapezius muscle is supplied by a transverse muscular branch arising from the occipital artery at the level of the mastoid process.²⁴ The vascularization of the middle portion of the trapezius muscle is supplied by the superficial cervical artery or by a superficial branch of the transverse cervical artery.²⁴ Finally, the lower third of the trapezius muscle is supplied by a muscular branch from the dorsal scapular artery, passing medial to the medial border of the scapula.²⁴

2.2. Function

To summarize descriptions of trapezius muscle effects on scapular motions (see Figure 6-3 for definitions), elevation of the scapula activates both upper and middle trapezius fibers;

adduction activates all of its fibers but depends primarily on middle trapezius fibers³; and rotation of the glenoid cavity upward involves the upper, middle, and lower fibers.

Figure 6-3. Illustration of terms used to describe movements of the right scapula, as seen from behind. Anterior tilt applies to the upper border of the scapula. Upward and downward rotation refers to direction of movement of the glenoid fossa. Medial and lateral rotation refers to direction of movement of the inferior angle. Retraction is scapular movement in a medial direction (toward the vertebral column), and protraction is movement of the scapula as a whole in a lateral direction (away from the vertebral column). Adapted and redrawn from Kendall FP, McCreary EK, Provance PG, et al. *Muscles, Testing and Function*. 5th ed. Baltimore, MD: Williams & Wilkins; 2005:303

Johnson et al,² in a report of a biomechanical and anatomic analysis of the trapezius muscle, state that the transverse orientation of the upper and middle trapezius fibers allows them to draw the clavicle, acromion, and spine of the scapula backward and medially (aided by the lower, or thoracic fibers) and propose that any upward action of the thin superior (nuchal) portion would be dissipated in the cervical fascia before these muscle fibers reached the clavicle (which they approach in almost a horizontal plane). These authors suggest that, in regard to upward rotation of the scapula, the upper and lower fibers participate in different ways in conjunction with the serratus anterior muscle. They state

that the lower fibers maintain the position of the deltoid tubercle, which becomes the axis of rotation, while the upper fibers exert an upward rotation moment about the axis to complement that of the serratus anterior muscle. Furthermore, they explain that the upper fibers of the muscle raise the scapula (indirectly) by rotating the clavicle about the sternoclavicular joint and exert no upward force on the scapula. This hypothesis was also supported by Guazzelli Filho et al,²⁵ who observed that the three portions of the trapezius muscle show increasing activity during abduction, adduction, and flexion-extension of the upper extremity. Nevertheless, electromyographic activity of the trapezius muscle is minimal when the upper extremity is unloaded, and heavy loads can be just suspended with a small contribution from the upper portion.²⁴

The mechanism by which the nearly horizontally oriented upper portion of the trapezius muscle can be effective in assisting the serratus anterior muscle is well explained.² By exerting a medially directed force on the clavicle, which must rotate around the sternoclavicular joint, it effectively draws the lateral end of the clavicle (to which it attaches) medially and upward. The resulting elevated position of the acromion transfers much of the weight being carried by the humerus to the sternoclavicular joint as a compressive force relieving the cervical spine of compression. The orientation of these fibers is nearly horizontal rather than vertical.

Middle Trapezius Fibers

The function of the middle trapezius muscle is somewhat debatable. This is in part due to the difficulty to isolate the muscle specifically with specific exercises.²⁸ Some authors describe the middle portion of the muscle as a scapular retractor,^{2,29} whereas others describe this portion of the muscle as a scapular retractor and stabilizer.^{24,30} Although this muscle is active during upward rotation of the scapula, that is, when performing an upward rotation shrug,³¹ the muscle cannot specifically perform upward rotation because the fibers of the middle trapezius are very close to the scapula's axis of rotation. With this short lever arm, it limits the muscle's ability to generate an upward rotary moment.² However, once upward rotation has been initiated, the middle trapezius has a better moment arm to contribute to the upward rotation motion.²

Rather than generating torque, research strongly supports the concept that the middle portion of the trapezius muscle, along with the lower portion of the muscle, assists in maintaining vertical and horizontal equilibrium of the scapula.^{2,32-34} Further supporting the stabilization function, it has been shown that this portion of the muscle activates before glenohumeral muscles with specific exercise.⁵ The middle portion of the trapezius muscle, along with the upper and lower portions, activate simultaneously in response to sudden movements.³⁵

Lower Trapezius Fibers

The function of the lower trapezius muscle is also somewhat debatable. This is in part due

to the challenge of isolating the muscle to determine its functions.²⁸ In addition, some authors consider the muscle to produce scapular adduction, depression, and rotation,³⁰ whereas others suggest the muscle is an important stabilizer of the scapula,^{2,5,35} which helps maintain vertical and horizontal equilibrium of the scapula.² On the basis of attachments of the lower trapezius muscle to the deltoid tubercle and the fact that the muscle fibers do not change length with upward rotation of the scapula, it would be a challenge for this muscle to generate any net torque for upward rotation.² This portion of the muscle assists with upward rotation, but more to resist the displacement of the serratus anterior muscle drawing the scapula laterally. With the stabilization component of the lower and upper portions of the trapezius (and serratus anterior) muscles exerting an upward rotation moment, upward rotation of the scapula is achieved.² Electromyographic studies support that this portion of the trapezius muscle is active, along with the upper and middle trapezius muscles, during upward rotation.^{10,31}

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 6.1 grossly represents the functional unit of the trapezius muscle.⁶ The trapezius, levator scapulae, rhomboids, and serratus anterior muscle combine in producing a variety of scapular rotations.²⁴

Box 6-1 Functional unit of the trapezius muscle

Action	Synergists	Antagonists

Entire Muscle

Acting bilaterally, the entire muscle assists extension of the cervical and thoracic spine.

Upper Trapezius Fibers

Acting unilaterally, the upper portion of the trapezius muscle extends and laterally flexes the head and the neck toward the same side and aids in extreme rotation of the head so that the face turns to the opposite side. It can draw the clavicle bone (and *indirectly* the scapula) backward and can raise them by rotating the clavicle at the sternoclavicular joint.² It usually helps (but can be trained not) to carry the weight of the upper extremity (indirectly through the shoulder girdle) during standing, or to support a weight in the hand with the arm hanging. In conjunction with the levator scapulae muscle and upper digitations of the serratus anterior muscle, the upper trapezius muscle provides the upper component of the force couple necessary to rotate the glenoid fossa upward. Ito²⁶ showed that during both flexion and abduction of the arm, the electromyographic activity of the upper trapezius increased progressively and became vigorous. In another study, when the arm was actively maintained in 90° of abduction, all subjects showed significant electromyographic evidence of fatigue within 1 minute, and, on average, in less than 30 seconds.²⁷

Upper Trapezius Fibers

The upper part of the trapezius muscle acts synergistically with the sternocleidomastoid muscle for head and neck motions, extension of the head, ipsilateral side bending, and contralateral rotation. Acting with the levator scapulae muscle, the upper portion of the

trapezius muscle elevates the scapula and the point of the shoulder; when acting with the serratus anterior muscle, the trapezius muscle rotates the scapula forward (upward) so that the arm can be raised above the head; and acting with the rhomboid muscles, the upper trapezius muscle retracts the scapula, bracing back the shoulder. With the shoulder fixed, the trapezius muscle may bend the head and neck backward and laterally.

Middle Trapezius Fibers

Middle fibers of the trapezius muscle are synergistic to the rhomboid muscles for adduction of the scapula and antagonistic to the serratus anterior and pectoralis major muscles. For upward rotation, the muscle is synergistic to the upper and lower trapezius and serratus anterior muscles.² The muscle is synergistic to the upper and lower portions of the trapezius muscle for scapular stabilization.^{2,5,32–35} Because of the stabilization component, the middle trapezius is also synergistic to the deltoid, rotator cuff, and long head of the biceps brachii muscles for elevation of the arm.

Lower Trapezius Fibers

In stabilizing the axis of rotation of the scapula muscle, these lower fibers are synergistic with the serratus anterior and upper and middle fibers of the trapezius muscle for upward rotation of the glenoid fossa of the scapula. These fibers are synergistic to the upper and middle trapezius fibers for scapular stabilization and with the deltoid, rotator cuff, and long head of the biceps brachii muscles for elevation of the arm.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Upper Trapezius Fibers

The upper portion of the trapezius muscle is one of the most common areas affected by TrPs. The upper portion of the trapezius muscle can exhibit TrPs in any fiber of the muscle belly. A common place, clinically observed, where TrPs can be mostly found is the anterior border of the muscle and involves the most vertical fibers that attach anteriorly to the clavicle. Based on clinical experience, TrPs in this area consistently refer pain unilaterally upward along the posterolateral aspect of the neck to the mastoid process. The referred pain, when intense, extends to the side of the head, centering in the temple and back of the orbit (Figure 6-4). It may also include the angle of the jaw,³⁶ also described as the region of the masseter.³⁷ Occasionally, pain extends to the occiput, and rarely some pain is referred to the lower molar teeth. Referred pain from TrPs in the upper portion of the trapezius muscle is a major source of tension-type headache.³⁸

Figure 6-4. Referred pain pattern from trigger points located in the most vertical fibers of the upper portion of the trapezius muscle. Solid red shows the essential referred pain zone whereas the stippling maps the spillover zone.

The upper portion of the trapezius muscle can also exhibit TrPs in the posterior border of the muscle, in the most horizontal fibers that attach to the spinous processes of the cervical spine. The referred pain of TrPs in this portion of the muscle is perceived in the posterior part of the cervical spine, with an abnormal sensation of tightness in the occipital region (Figure 6-5, pattern on left of figure). This TrP is highly frequent in patients with mechanical neck pain.³⁹

Figure 6-5. Left side of figure shows the referred pain pattern of TrPs in the posterior and more horizontal fibers of the upper portion of left trapezius muscle. Right side of figure shows the referred pain pattern of TrPs in a right lower trapezius muscle.

Middle Trapezius Fibers

Trigger points in the middle trapezius muscle can refer superficial burning pain between the medial scapular border and the spinous processes of C7-T3 vertebrae (Figure 6-6, pattern on right of figure). This reported burning sensation should not be confused with pain of cervical origin, which can also refer to this area.^{1,9,40} Trigger points can also refer an aching pain to the top of the shoulder by the acromion (Figure 6-7, pattern on left of figure). This pattern overlaps with the pain referral pattern of the lower portion of the trapezius muscle (Figure 6-5, pattern on right of figure). The middle portion of the muscle can also produce an autonomic sensation whereby the patient reports a “shivery” sensation with associated piloerector erection on the lateral aspect of the ipsilateral arm (Figure 6-7, pattern on right of figure).

Figure 6-6. Left side of figure shows referred pain pattern of TrP in the region of lateral attachment of the left lower trapezius. Right side of figure shows referred pain pattern of TrP region in the midfiber region of the middle portion of the trapezius muscle.

Figure 6-7. Referred pain pattern of TrPs at the lateral attachment region of the left middle trapezius muscle. Trigger points in the middle trapezius muscle can refer pilomotor activity, or “gooseflesh,” as identified on the right upper limb by red “>” symbols.

Lower Trapezius Fibers

Trigger points in the lower portion of the trapezius, although common, are frequently overlooked as a source of cervical pain. They have been shown to refer pain to the high cervical region of the paraspinal muscles, adjacent to the mastoid area (Figure 6-5, pattern on right of figure).^{41, 42} The muscle can also refer pain to the acromion⁴¹ and over the suprascapular region.⁴³ Trigger points in the muscle closer to the attachment on the scapula (Figure 6-6, pattern on left of figure) can refer a burning pain along and medial to the medial border of the scapula. This reported burning sensation should not be confused with pain of cervical origin, which can refer to the same area.^{1, 9, 40}

3.2. Symptoms

Upper Trapezius Fibers

Patients with TrPs in the trapezius muscle can exhibit pain in the head, cervical spine, or the back, depending on the affected portion of the muscle. It seems that TrPs in the upper portion of the trapezius can contribute to tension-type headache,³⁸ migraine⁴⁴ or neck pain.^{13,39} In patients with chronic neck and head pain symptoms, the pain pattern is likely to be a composite of referred pain from several neck and masticatory muscles. Patients with TrPs in the upper portion of the trapezius muscle can exhibit restricted neck range of motion, or pain on motion, but this usually occurs when the head and neck are almost fully rotated actively to the opposite side, which contracts the muscle in a shortened position. The most restricted movement is usually lateral flexion of the head and neck away from the involved upper trapezius muscle. If a TrP in trapezius muscle is combined with the presence of other muscles including the levator scapulae or splenius cervicis, the patient may develop an acute “stiff neck.”⁴⁵ This painfully limits rotation of the head toward the same side, which elongates the upper trapezius muscle.

With entrapment of the greater occipital nerve as a sequela to prolonged activation of upper trapezius muscle TrPs, patients report numbness, tingling and burning pain in the scalp over the ipsilateral occipital region (“occipital neuralgia”) in addition to headache. It is interesting to observe that the referred pain from TrPs in the upper portion of the trapezius muscle resembles the topographical pain pattern of greater occipital nerve compression, so careful examination of both muscle and nerve tissues is highly relevant. Patients with nerve entrapment usually prefer cold rather than heat. Entrapment symptoms of the greater occipital nerve apparently develop when TrP activity in one of the muscles that it penetrates (the semispinalis capitis or the upper trapezius muscles) produces taut bands of muscle fibers that compress the nerve as it penetrates the muscle.

Middle Trapezius Fibers

Patients with TrPs in the middle trapezius muscle can report deep burning interscapular pain. Similar symptoms can also originate from the cervical or upper thoracic spine and should be ruled out. Therefore, in addition to examining the middle trapezius muscle for TrPs, clinicians should examine the cervical/thoracic zygapophyseal joints. Trigger points referring to the acromion area create pain and tenderness in the region. Patients will report that they have intolerance to pressure from bags on their shoulders⁴⁶ or discomfort with wearing heavy coats. Trigger points can also produce a referred autonomic response that is described like “shivers running up and down the spine” when a fingernail scrapes across the blackboard.

Lower Trapezius Fibers

Trigger points in this muscle can cause neck,⁴² suprascapular, interscapular, or acromial pain with little, if any, restriction of motion. Trigger points often induce associated TrPs in the upper back and neck muscles. This muscle is often forgotten about as a source of upper neck pain, which can contribute to less-than-optimal treatment results until TrPs in this

muscle are treated.⁴² Clinicians should consider the presence of TrPs in the lower portion of the trapezius muscle in patients with neck pain exhibiting a rounded shoulder position and a thoracic kyphosis because the lower fibers of the trapezius muscle are stretched in this position.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper assessment and examination of the trapezius muscle, the clinician should assess accessory motion of the sternoclavicular, acromioclavicular, and glenohumeral joints because hypomobility in all or some of these joints can contribute to scapular dyskinesia.⁴⁷

Upper Trapezius Fibers

Trigger points in the upper fibers of the trapezius muscle typically do not contribute to weakness of the muscle.⁷ This is likely because the upper trapezius muscle typically tends to be hyperactive and tense.⁴⁸ In fact, patients typically present with an elevated shoulder on the side of the tense upper trapezius muscle with a slight tilt of the neck toward the affected side. Trigger points in this muscle can also contribute to reduced cervical range of motion,^{49,50} neck pain,^{15,50,51} and shoulder impairment.⁵² Cervical range of motion is particularly affected in lateral flexion of the head and neck away from the involved upper trapezius. Active rotation of the head to the opposite side is usually painful at the extreme range of motion because the muscle contracts strongly in this most shortened position. Active rotation to the same side is usually pain free, unless either the levator scapulae muscle on the same side, or the opposite upper trapezius muscle, also have TrPs. In addition, the increased intramuscular electromyographic activity of latent TrPs in the upper trapezius muscle is significantly greater with shoulder abduction, suggesting that it can impair the synergies of muscles during osteokinematic motions.¹⁴ Other studies also support the theory of alteration in muscle activation patterns from TrPs.^{53,54}

Middle Trapezius Fibers

The patient with pain arising from the middle trapezius muscle is likely to have a rounded shoulder posture secondary to shortening and/or TrPs of the antagonistic pectoralis muscles. A shortened pectoralis major muscle maintains the humerus in internal rotation and adduction, which causes the scapula to abduct away from the spine and alter the length tension relationship of the muscle.⁴⁸ As a result, this forward-head posture can reduce the muscle's ability to fire properly.⁵⁵ Although not specific to the pectoralis major and middle trapezius muscles, research has shown that latent TrPs affect reciprocal inhibition.⁵⁴ Resultantly, TrPs in the pectoralis muscles could influence how the middle trapezius

muscle fires.

Lower Trapezius Fibers

The fibers of the lower trapezius muscle are often more susceptible to inhibition than the upper trapezius muscle. This weakness can be due to a structural lesion or adaptive changes.⁴⁸ Tightness of the pectoralis minor muscle can be one factor contributing to the inhibition of lower portion of the trapezius muscle. The pectoralis minor muscle is known to contribute to altered scapular kinematics^{47,56}; as a result, this can impair firing of the scapular muscles, including the lower trapezius muscle.⁵⁷ Weakness of this muscle can also be associated with neck pain.⁵⁸ It is known that TrPs can contribute to altered muscle firing.^{14,53,54} Trigger points can also contribute to inhibition of muscles, as it has been shown that utilizing dry needling immediately improves the firing of scapular muscles with latent TrPs.⁵³

Trigger points in the lower fibers of the trapezius muscle may affect upward rotation of the scapula because of impairment of the stabilization function. If the lower trapezius muscle is inhibited and weak from the activity of TrPs, the scapula may be elevated and the upper part tilted forward (coracoid process tilted forward and downward), and the patient will exhibit a rounded shoulder posture.

3.4. Trigger Point Examination

Manual examination of TrPs requires adequate manual skills, training, and clinical practice to develop a high degree of reliability in the examination. To determine the most useful diagnostic criteria for TrPs, Gerwin et al⁵⁹ tested the reliability with four experienced physicians and could identify five characteristics of TrPs in five pairs of muscles (one was the upper trapezius muscle). Four criteria are highly reliable in this muscle: the detection of spot tenderness, palpation of a taut band, the presence of referred pain, and reproduction of the subject's symptomatic pain (agreement 90% to perfect and kappa 0.61-0.84). Identification of a local twitch response by manual palpation was unreliable in this muscle. When present, however, a local twitch response is a strong confirmatory finding and is especially valuable when needling TrPs therapeutically. A more recent study found a moderate to high intrarater reliability (ICC ranging from 0.62 to 0.81) for the diagnosis of TrPs in the upper trapezius muscle with a limit of agreement around 26 mm.⁶⁰ No reliability studies have been performed on the middle and lower portions of the trapezius muscle.

Upper Trapezius Fibers

Although no exact location of TrPs should be considered when clinicians examine the upper trapezius muscle, a recent cadaver study has shown that some locations may be more susceptible for TrP development because these are the areas where the spinal accessory nerve innervates the muscle.⁶¹

For clinical examination of the anterior and most vertical fibers of the upper trapezius muscle, the patient is supine, or possibly prone. Supine is preferred because the upper trapezius muscle is more relaxed. The upper portion of the trapezius muscle is placed on moderate slack by bringing the ear slightly toward the shoulder on the same side. In a pincer grasp, the entire mass of the free margin of the upper trapezius muscle is lifted off the underlying supraspinatus muscle and apex of the lung (Figure 6-8A and B). Then the muscle is firmly rolled between the fingers and thumb to palpate the taut bands. With this cross-fiber pincer palpation, a local twitch response can be easily provoked with snapping palpation and strumming of the taut band. In fact, the local twitch response can be easily appreciated by the clinician. After identifying the taut band, these fibers should be searched for a spot eliciting local and referred pain to the neck or the head.

Figure 6-8. Positioning of the patient and technique for examining TrPs in the trapezius muscle: A, Cross-fiber pincer palpation for TrPs in the left upper trapezius muscle, patient

supine. B, Cross-fiber pincer palpation for TrPs in the right upper trapezius muscle, patient prone. C, Cross-fiber flat palpation for TrPs in the midfiber portion of the right middle trapezius muscle, patient prone. D, Cross-fiber flat palpation for TrPs in the right lower trapezius muscle, patient prone.

For clinical examination of the posterior and horizontal fibers of the upper trapezius muscle, the patient is prone (image not shown). Trigger points are identified by a similar pincer technique as for the anterior fibers. Patients with firmer tissue require cross-fiber flat palpation.

Middle Trapezius Fibers

Prone positioning is one option for examination of the middle portions of the trapezius muscle (Figure 6-8C). Alternatively, the patient can sit with the arms folded across the front of the body to abduct the scapulae and flex the thoracic spine. Cross-fiber flat palpation identifies taut bands in the muscle by rolling them against the underlying ribs. The firm bands usually exhibit visible local twitch responses to snapping palpation of the TrP. A preferred way to palpate the muscle is in the prone position. In the prone position, the muscle is more relaxed. Research shows that the seated versus prone position influence the stiffness of the muscle.⁶² In the prone position, the muscle can be palpated in a cross-fiber pincer palpation or with a flat cross-fiber palpation similar to the seated position. The type of palpation would be determined in part by which part of the muscle is being assessed and the muscle thickness of the patient.

There are three common areas that TrPs can be found in the middle trapezius muscle. These areas have recently been supported by a cadaver study showing that they are the same locations where the spinal accessory nerve innervates the muscle.⁶¹ The first area is about 1 cm (½ in) medial to the scapular attachment of the levator scapulae muscle (Figure 6-8C). The second area is in the lateral attachment region of the middle trapezius (Figure 6-6, left side). A cross-fiber flat palpation is necessary in this area. The third area is over the midmuscle region of the middle trapezius muscle (Figure 6-6, right side), which can be palpated with either a cross-fiber flat or pincer palpation.

Lower Trapezius Fibers

The patient is positioned prone for examination of the lower trapezius muscle (Figure 6-8D). Alternatively, the patient can sit with the arms folded across the front of the body. According to Simons et al,⁶ this position takes up the tissue slack, preventing the TrP within the taut band from being missed. Cross-fiber flat palpation is performed across the muscle. The preferred way to palpate the muscle is in the prone position. In the prone position, the muscle is more relaxed. Research shows that the seated versus prone position influence the stiffness of the muscle.⁶² In the prone position, the muscle can be palpated in a cross-fiber pincer palpation, or similarly as in the seated position with a cross-fiber flat palpation. In either position, the entire muscle should be examined for TrPs.

There are two common areas that TrPs can be found in the lower trapezius muscle. These areas have recently been supported by a cadaver study showing that they are the same locations where the spinal accessory nerve innervates the muscle.⁶¹ The first is close to where the fibers cross the medial border of the scapula, or sometimes at or below the level of the inferior angle of the scapula (Figure 6-5, right side). The second is close to the lateral musculo-tendinous junction where the lower trapezius muscle attaches to the deltoid tubercle of the spine of the scapula (Figure 6-5, left side). Here TrPs have been noted to feel like thicker bands within the tissue.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

Any posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the trapezius muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading (Gerwin et al. 2004). Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. In addition, sudden trauma, such as whiplash in an auto accident,^{13, 64} falling off a horse, or falling down from steps can also cause TrP formation.

Upper Trapezius Fibers

The upper trapezius fibers' function of neck stabilization is commonly overloaded by tilting of the shoulder girdle axis due to a lower limb-length inequality or small hemipelvis (body asymmetry). The limb asymmetry tilts the pelvis laterally, which bows the spine into a functional scoliotic curve and, in turn, tilts the shoulders, causing one to sag. The upper trapezius muscle must work constantly to keep the head and neck vertical and the eyes level.

The normally minimal antigravity function of the upper trapezius muscle is overstressed by any position or activity in which the muscle helps to carry the weight of the arm for a prolonged period: using the phone or sitting without armrest support, particularly when the upper arms are congenitally short; holding the arms elevated to reach a high keyboard or a high drawing board; or working with sewing material on the lap with the elbows unsupported. In fact, trapezius myalgia is usually considered a work-related disorder.^{11, 65-67}

The upper trapezius muscle may be strained by obvious acute gross trauma, but more often it is strained by chronic injury due to overload or microtrauma that may not be so obvious. Such injury can be caused by clothing and accessories, by pressure from tight narrow bra straps supporting large breasts, by the shoulder strap of a ponderous purse,⁴⁶ a heavy backpack, or by a heavy coat. It may also be caused by a sustained load in habitual elevation of the shoulders, as an expression of anxiety or other emotional distress, during long telephone calls, playing the violin, or by rotation of the head *far* to one side in a fixed

position (holding the head turned to converse with a person seated at the side, or sleeping prone with the head strongly rotated).

Occupational overload is receiving increasingly serious attention; however, the important contribution of TrPs as a major cause of the pain is not yet generally recognized. In a prospective study of employees,⁶⁵ the authors recorded the electromyographic activity of the upper (acromial) fibers of the middle trapezius muscle doing repetitive tasks. Elevated static and mean electromyographic activity levels and fewer electromyographic gaps of at least 0.6 second duration correlated significantly with future reports of neck and shoulder pain. These subjects, were not examined for TrPs, but chronic overload such as this without adequate periods of relief, activates TrPs. A similar prospective 1-year study of 30 female packers doing repetitive light work⁶⁶ revealed that within 1 year, 17 of the 30 developed sufficient work-related trapezius myalgia to be classified as patients, with a median time of onset of 26 weeks. The authors did not address the cause of the pain, which was likely TrPs in many subjects. A more recent study by Hoyle and colleagues⁶⁸ showed that TrPs develop in subjects after 1 hour of typing regardless of the high or low visual and postural stresses placed on each individual.

Other factors may activate upper trapezius TrPs. Armrests that are too *high* push the scapulae up and shorten the upper trapezius for long periods. The muscle's accessory function of head rotation can be overused, and the muscle overstressed, by the quick repetitive movement of flicking long hair out of the eyes.

Upper trapezius TrPs may also be activated by, and remain as sequelae to, cervical radicular pain.⁶⁹

Middle Trapezius Fibers

This part of the muscle can be overloaded eccentrically with upright row exercises,⁷⁰ so caution should be considered when considering this exercise and the amount of weight used. The fibers of the middle trapezius muscle also becomes overloaded when the arm is held up and forward for a long time, that is, prolonged reaching activities or when the driver of a car holds the hands on top of the steering wheel. Sustaining this position overloads the pectoralis major fibers, which are prone to develop TrPs, which increases their tension. Trigger points in the antagonistic muscles are known to contribute to unbalanced muscle activation and fine movement control.⁵⁴ As a result, TrPs in both muscles need to be considered when either one is impaired. In addition, TrPs in the pectoralis major muscle can contribute to shortening of the muscle. This maintains the humerus in internal rotation and adduction, which causes the scapula to abduct away from the spine.⁴⁸ Resultantly, the middle trapezius fibers may be lengthened and weak, contributing to the development of TrPs and associated pain.

Lower Trapezius Fibers

The lower fibers are strained during prolonged bending and reaching forward while sitting (to reach the desk when the knees lack space under its surface) and by supporting the chin

on the hand, while resting the elbow on the front of the chest because armrests are missing. An increased thoracic kyphosis combined with a rounded shoulder posture is also a good perpetuating and promoting factor for TrP development in the lower portion of the trapezius muscle.

4.2. Associated Trigger Points

It has been shown that associated TrPs can develop in the referred pain areas caused by TrPs⁷¹; therefore, muscles in the referred pain areas for each muscle should also be considered. In the presence of TrPs in the upper portion of the trapezius muscle, associated TrPs are likely to develop in the functionally related levator scapulae, sternocleidomastoid, and contralateral trapezius muscles, and also in the ipsilateral supraspinatus and rhomboid muscles. Associated TrPs may appear in the temporalis and occipital muscles, which lie within the zones of pain referred from TrPs in the upper trapezius muscle. Hong⁷² identified a number of associated TrPs that were inactivated by inactivating TrPs in the upper trapezius muscle. The associated TrPs appeared in the temporalis, masseter, splenius, semispinalis, levator scapulae, and rhomboid minor muscles.

When the middle trapezius muscle is involved, associated TrPs can develop in the rhomboids, serratus posterior superior, thoracic paraspinals at the levels of T1-T6, and the supraspinatus muscles. Outside of the referred pain areas, other muscles that could also be involved include the antagonistic pectoralis major and pectoralis minor muscles.

Trigger points in the lower portion of the trapezius muscle are prone to induce associated TrPs in the upper trapezius, supraspinatus, and sometimes in the levator scapulae and the posterior cervical muscles. For this reason, one should routinely check the lower trapezius muscle for TrPs, especially when the upper trapezius TrPs responds poorly to treatment.⁴² Keep in mind, however, that a TrP in the lower trapezius muscle may itself be an associated TrP of a TrP in the latissimus dorsi muscle.

4.3. Associated Pathology

Myofascial pain in the trapezius muscle is highly prevalent and comorbid with several underlying medical conditions. Patients with widespread chronic pain that includes multiple regional involvements should be clinically examined for the diagnosis of fibromyalgia since these patients exhibit a higher number of TrPs in this muscle.⁷³

Upper Trapezius Fibers

Trigger points in the upper portion of the trapezius muscle are associated with medical conditions such as neck pain, temporomandibular pain disorders, or headaches. Shoulder pain has also been associated with a high prevalence of TrPs in the upper trapezius muscle.⁷⁴ A common cause of upper trapezius muscle (and other muscles) TrPs is the impact stress from a whiplash injury.^{13, 64} Furthermore, pain originating from TrPs in the upper trapezius and the splenius capitis muscles can confusingly simulate occipital neuralgia

because the greater occipital nerve crosses these muscles.⁷⁵

The symptoms caused by upper trapezius TrPs may be closely associated with, and confusingly similar to, somatic or articular dysfunctions from C2 to C4. Commonly, one or more of these restricting articular dysfunctions and upper trapezius TrPs coexist, and both must be treated. In fact, Fernández de las Peña et al⁷⁶ found a clinical association between the presence of TrPs in the upper trapezius muscle and intervertebral joint dysfunctions at C3-C4 levels.

Hypermobility of the C4 segment has been observed clinically to be associated with the upper trapezius muscle dysfunction. Joint stress that causes referred pain can involve the upper trapezius muscle secondarily, and this muscle often becomes hyperirritable and develops TrPs. An upper trapezius muscle source of pain may be differentiated from a joint source by testing for pain on side bending of the cervical spine and then (1) passively support the patient's upper limb and side-bend the cervical spine again; if the pain is markedly reduced or absent, the problem may be in the trapezius muscle; and (2) apply pressure downward on the shoulder (as in lengthening the upper trapezius muscle); if there is an increase in pain, the upper trapezius muscle may be the source of the problem. If *neither* of these tests changes the pain, the cervical joints (perhaps C4) may be the problem. In addition, different manual testing of joint mobility are generally applied in these cases.

Trigger point involvement of the upper trapezius, splenius capitis and cervicis, levator scapulae, and sternocleidomastoid muscles must be distinguished from spasmodic torticollis (cervical dystonia), which is a neurologic condition characterized by involuntary dystonic movements of the head^{77,78} that can be genetic, acquired, or idiopathic.⁷⁹ The muscles most commonly involved in this condition include the sternocleidomastoid, trapezius, scalenes, and platysma,⁸⁰ thus making the differential diagnosis of this condition (versus TrPs) essential to ensure proper care. With spasmodic torticollis, hypertrophy of the muscles may develop.⁷⁷ In contrast, the apparent shortening of a muscle due to TrPs does not cause hypertrophy, nor does it cause involuntary movements of the head.

Middle Trapezius Fibers

The main underlying medical conditions related to dysfunction of the middle portion of the trapezius muscle are related to changes in thoracic curvature, for example, scoliosis or kyphosis, osteoporosis, tumors, fractures, and the like. The cervico-thoracic junction is a troublesome transitional vertebral area that commonly develops dysfunctions, primarily of C6, C7, T1, and occasionally T2. Commonly, these dysfunctions are associated with adduction of the scapulae and elevation of the first rib on the same side.

Lower Trapezius Fibers

Articular dysfunctions associated with interscapular pain and lower trapezius TrPs⁸¹ may extend from T4 to T12. There is usually a central painful segment near T6 or T7, which is the primary structural dysfunction that must be treated along with inactivation of the TrPs. The dorsal scapular nerve⁸² and cervical spine^{1,9,40,83} should also be considered in patients

with interscapular pain.

5. CORRECTIVE ACTIONS

Correction of poor posture (particularly rounded shoulder posture with an excessive forward head posture) and maintenance of good posture are primary in any treatment approach, both for initial relief of pain and for lasting relief. Refer to Chapter 72 for discussions of posture and body mechanics.

The upper trapezius muscle is generally recognized as prone to hyperactivity and increased tension, whereas the middle and lower trapezius muscles tends to be just the opposite, inhibited, weak, and overstretched.⁴⁸ Self-treatment that depends primarily on stretch can be counterproductive in muscles prone to inhibition and weakness and are not recommended. Therefore, we emphasize for the middle and lower portions of the trapezius muscle the application of massage to the taut band, TrP pressure release, and other techniques, carefully avoiding excessive stretch. The use of TrP self-pressure release tools can be useful for treatment of these muscles. Specific corrective actions for each portion of the trapezius muscle are described below.

Upper Trapezius Fibers

Patients with TrPs in the upper trapezius muscle should not sleep on a foam pillow; its springiness can aggravate TrP symptoms. Antigravity stress on the upper trapezius muscle in normally proportioned individuals is corrected by selecting chairs with armrests of the correct height to provide elbow support or by building up the height of the armrests, if they were designed too low (refer to Chapter 79).⁸⁴ Every seated person benefits by learning to distinguish between chairs that fit and chairs that enforce poor posture, which can aggravate the muscles.⁸⁵

Patients who are intensely preoccupied with what they are doing are susceptible to lose track of time and maintain an undesirable posture. This can happen while engrossed at a computer or leaning forward over a desk for a prolonged period while writing. Trigger points have been shown to develop with 1 hour of typing.⁶⁸ These individuals can relieve muscle tension every 20 or 30 minute, without interrupting the train of thought, by setting an interval-timer for that length of time and placing it across the room. Then they must get up and can stretch while they walk to turn off the buzzer and reset the timer. Downloadable applications from the Internet can be set on a computer as well for break reminders.

Muscles are more tolerant of prolonged activity if they have frequent short breaks permitting relaxation. A few cycles of active range of motion makes the break more effective. In the case of the upper trapezius muscle, this may be achieved by slowly rotating the shoulders in a full circle several times, first in one direction and then in the other.

For office workers, a common source of stress to the upper trapezius muscle is a keyboard set so high that the shoulders are maintained in an elevated position. Lowering the keyboard eliminates excessive sustained electromyographic activity of the upper

trapezius muscle.⁸⁶ The keyboard should be placed at an appropriate height. If the keyboard height is properly adjusted but the subject leans forward away from the backrest, the upper trapezius muscles may still be overloaded (refer to Chapter 76). Leaning back against the backrest of a chair so that it supports the scapulae can provide much relief. The individual must lean back and allow the shoulders to drop down so the backrest supports them. In most chairs, a small cushion for lumbar support facilitates good posture. If modification of sitting postures is insufficient, using an adjustable standing desk is an alternative. Refer to Chapter 76 for additional suggestions regarding the correction of poor posture and ergonomics.

For patients who have long conversations on the telephone or cellphone, a head set or hands-free setting relieves the neck and arm muscles from the strain of holding a phone.

When conversing with someone, the patient should turn his or her chair to face the other person or turn the entire body and not just the head.

It is best to try to avoid sleeping prone when the upper portion of the trapezius muscle has TrPs. If one does sleep prone, a pillow placed under the shoulder and chest on the same side to which the face is turned helps to reduce rotation of the neck. A semiprone position, achieved by flexing the knee and hip of the side toward which the face is turned, also helps by partly rotating the torso.

Objectionable pressure on the trapezius muscle by a thin, tight bra strap should be relieved by wearing a wider, nonelastic bra strap, and/or by slipping a soft shield under the strap to distribute the pressure. Sliding the strap laterally to rest on the acromion relieves pressure on the muscle. A professional bra fitting may be indicated if TrPs in the upper trapezius muscle are resistant to treatment. A strapless bra that constricts too tightly around the ribs may cause comparable pressure activation of TrPs in the latissimus dorsi, serratus anterior, or serratus posterior inferior muscles.

Supporting and/or offloading the upper trapezius muscle during seated activities may be beneficial for decreasing TrP activity (Figure 6-9). A recent study also demonstrated that tensioned and nontensioned taping across the upper portion of the trapezius muscle reduces its activity during a typing task.⁸⁷

Figure 6-9. Ergonomic solutions for the upper trapezius muscle. A, Effective support of the arms by armrests of a desk chair. B, Desk chair with adjustable armrests at an appropriate height to support the upper extremities during desk tasks. C, Offloading the left upper extremity by raising the left armrest. D, Desk chair with left armrest raised to offload the left upper trapezius muscle.

Middle Trapezius Fibers

When the arm must be held out in front of the body for long periods of time, some form of elbow rest should be devised. The middle trapezius exercise (Figure 6-10) is tailored to maintain full active range of motion in both the middle and lower trapezius muscles. The patient is instructed to lie supine on the floor. To reduce strain on the lower back, the knees should be bent so the feet are on the floor. The core muscles should also be activated to prevent arching of the back as the arms move. Place the elbows, forearms, and palms of the hands together in front of the abdomen (Figure 6-10A). Keep the elbows tightly together as long as possible while raising the forearms over the face (Figure 6-10B). Then, drop the forearms past the ears to the floor (Figure 6-10C). Keeping the back of the elbows and wrists in contact with the floor, swing the arms down against the sides of the body (Figure 6-10D and E). Pause and relax, while taking several slow deep breaths. Repeat the cycle.

Figure 6-10. The middle trapezius exercise helps to maintain full range of motion in the middle and lower parts of the trapezius muscle by abducting and rotating the scapulae. Movements progress from (A) through (E). When completed, the patient pauses, breathes deeply to relax, and repeats the sequence.

The importance of checking both pectoral muscles for tightness (and TrPs) cannot be overemphasized. Most commonly, middle trapezius weakness and TrPs are from overload and are secondary to other causes. Unless the tightness of the thoracic anterior muscles causing the problem is effectively addressed, the patient will continue to have trouble. The pectoral fibers can be stretched by performing the doorway stretch exercise (refer to Figure 49.10). The middle hand position of this exercise specifically stretches the sternal division of the pectoralis major muscle, which most directly opposes the middle trapezius muscle. An alternative to the doorway stretch exercise is to lie on a foam roller in the supine position with the arms elevated to different positions (refer to Figure 42-11). To treat TrPs of the pectoralis muscle, TrP self-pressure release tools can be used. Each release procedure is followed promptly by full active range of motion and moist heat to the treated region.

The middle trapezius muscle responds well to TrP pressure release by the operator or self-release by the patient using a cold tennis ball (Figure 6-11) or other types of TrP self-pressure release tools. Each release procedure is followed promptly by full active range of motion and moist heat to the treated region.

Figure 6-11. Trigger point self-pressure release of the middle trapezius muscle with a cold tennis ball.

Lower Trapezius Fibers

Proper workstation posture can reduce symptoms arising from TrPs in the lower trapezius muscle. Every patient should arrange seated workspace to provide adequate room for the knees underneath the desk or table. The chair should be pulled close enough to the

workspace so that the patient can lean back firmly against the backrest; both elbows should rest on the work surface or on short armrests of about the same height as the desk surface. The middle trapezius exercise (Figure 6-10) is also helpful for at-home maintenance of full range of motion in the lower trapezius muscle.

The lower portion of the trapezius muscle is often the key to successful treatment of the upper trapezius, levator scapulae, and some neck extensor muscles; these muscles lie in the referred pain zone of the lower trapezius muscle and may develop satellite TrPs to the key lower trapezius TrP. The lower trapezius muscle itself (and by extension the above-mentioned muscles) may develop pain and TrPs because of TrP tension in the antagonistic pectoralis major (refer to Chapter 42) and pectoralis minor muscles (refer to Chapter 43). When the pectoral muscles are involved, their full normal resting length must be restored in order for the lower trapezius muscle to be relieved of overload. The pectoral fibers can be stretched by performing the in-doorway stretch exercise (refer to Figure 42-10) or lying supine on a foam roller (refer to Figure 42-11). To treat TrPs of the pectoralis muscles, TrP self-pressure release tools can be used. Each release procedure is followed promptly by full active range of motion to the treated region.

Because the lower trapezius muscle is often weak, the aim is not primarily stretch but rather release of tension in the taut band. Toward this aim, the patient can apply self-TrP pressure release by lying on a tennis ball that is positioned to press on the TrPs. Other types of TrP self-pressure release tools can also be used to apply pressure to the TrPs (Figure 6-12). Each release procedure is followed promptly by full active range of motion and moist heat to the treated region.

Figure 6-12. Trigger point self-pressure release of the lower trapezius muscle using a TrP release tool.

Performing a scapular posterior tilting motion (Figure 6-13) in conjunction with

assisted pectoralis minor stretching has also been shown to be effective to improve activation of the lower trapezius muscle.⁵⁷

Figure 6-13. Scapular posterior tilting. The patient starts in the quadrupedal position and rocks back slowly to sit on his heels. With the arm elevated to approximately 145°, elbow extended, and the thumb side of the wrist facing upward, the arm is actively lifted until it is lifted to the level of the ear. The position is held for 5 seconds before lowering the arm back down to the starting position.

When using a moist heating pad or hot pack for relief of pain referred from TrPs in the lower fibers of the trapezius muscle, the patient should apply the heat to the mid back area where the TrPs are located, rather than solely to the suprascapular region and neck where pain is felt. The patient should never lie on the pad; instead the pad should be placed on the back while the patient is semiprone.

Women should consider wearing a brassiere with crossed versus parallel straps as this has been shown to improve activity of the lower trapezius muscle and reduce activity of the upper trapezius muscle.⁸⁸

Sternocleidomastoid Muscle

“Migraine and Sinus Headache Imposter”

Michelle Finnegan and Susan H. Rightnour

1. INTRODUCTION

The sternocleidomastoid (SCM) muscle is an important muscle of the neck for posture and control of head movement and is commonly seen in clinical practice to have trigger points (TrPs). It is composed of two heads, sternal and clavicular, which both originate from the mastoid process. The sternal division inserts onto the manubrium of the sternum, whereas the clavicular division inserts along the medial third of the clavicle. The muscle is innervated by the spinal accessory nerve and receives vascularization from branches of the occipital and posterior auricular arteries for the upper portion of the muscle, while the middle portion is supplied by the superior thyroid artery and the lower portion is supplied by the suprascapular artery. Bilaterally, the muscle functions to flex the head against gravity. It also assists with forced inspiration when the head is fixed. Unilaterally, the muscle functions to side bend the head ipsilaterally and rotate the head contralaterally. The pain referral of the sternal division of the muscle is distributed over the upper portion of the sternum, throughout the face, the pharynx and the back of the throat, the chin, the occipital area, and the vertex of the head. The clavicular division of the muscle refers to both the sides of the frontal region of the head, unilaterally deep in the ear, and the posterior auricular region. Trigger points in this muscle are associated with many different conditions including temporomandibular dysfunction whiplash-associated disorders, mechanical neck pain, episodic migraine, cervicogenic headache, and tension-type headache. Corrective actions for this muscle include avoiding prolonged positions with the head turned to one side, sleeping with proper pillow support, stretching of the muscle by turning the head toward the restricted side with a chin retraction, or passively stretching the muscle in supine over a pillow.

2. ANATOMIC CONSIDERATIONS

As stated earlier, the SCM muscle has two divisions with differing caudal attachments. They are separated near their attachments by a triangular interval, the lesser supraclavicular fossa. This muscle divides the neck into anterior and posterior triangles. Its central region is narrow and dense becoming broader and thinner at each end. It acts as a protective barrier to the vital structures that lie beneath it, including the common carotid artery, accessory nerve, brachial plexus roots, cervical plexus nerves, and cervical lymph nodes.¹ Cephalad, the two divisions blend to form a common attachment on the mastoid process (Figure 7-1). The relative size of the two divisions and the space between them at the clavicle are variable. Due to each head of the muscle having a different direction of pull, it may be classified as “cruciate” and slightly “spiralizer.”¹ Anomalies of the SCM attachments have been reported in the literature including the presence of a third accessory head that lies between the sternal and clavicular heads,^{2,3} the absence of the SCM muscle,⁴ and a blending of the SCM muscle with the platysma muscle.⁵

Figure 7-1. Attachments of the two divisions of the sternocleidomastoid muscle (dark red). The sternal division is more anterior, more diagonal, and more superficial than the clavicular division. The bones to which the muscle attaches show darker stipples.

Sternal Division

The sternal fibers are the more medial, diagonal, and superficial fibers of the two heads of the SCM muscle, attaching to the anterior surface of the manubrium sterni. They ascend

posterolaterally and attach above by a strong tendon to the lateral surface of the mastoid process and by a thin aponeurosis to the lateral half of the superior nuchal line of the occipital bone (Figure 7-1). The sternalis muscle may extend downward over the anterior chest, appearing like a continuation of the sternal division of the SCM muscle (see Chapter 43).

Clavicular Division

The clavicular fibers are the more lateral and deeper of the two heads of the SCM muscle distally. This portion of the muscle is variable in width and attaches below to the superior border of the anterior surface of the clavicle, along its medial third. It ascends almost vertically, attaching above to the same bony structures, as does the sternal division (Figure 7-1).¹

The clavicular fibers are mainly directed to the mastoid process, whereas the sternal fibers are more oblique and superficial extending to the occiput. The thick, round belly of this muscle is formed by the blending of the two heads as the clavicular portion spirals behind the sternal head.¹

2.1. Innervation and Vascularization

The fibers of the SCM muscle (and some of the trapezius muscle) have an unusually close association with the brain stem, which helps to account for its remarkable functional concomitants. The SCM muscle is innervated by the spinal (external) portion of the accessory nerve (cranial nerve XI). This nerve originates in the spinal nucleus of the spinal cord of the upper five⁶ or six^{7,8} cervical segments. The fibers from the cervical segments merge to form a trunk. The spinal root enters the posterior fossa of the cranium through the foramen magnum. Here, the spinal root briefly joins the cranial (internal) root to form a single nerve trunk, the accessory nerve. The accessory nerve exits the jugular foramen, heading toward the retrostyloid space.⁷ From here the nerve divides into the cranial and spinal portions of the accessory nerve. The spinal accessory nerve typically passes laterally to the internal jugular vein.⁹⁻¹¹ Although less frequent, the nerve can also pass medially,¹¹ through,^{11,12} or split around¹¹ the internal jugular vein. The nerve then descends in an oblique manner, staying medial to the styloid process, stylohyoid, and digastric muscles.⁶ From here the nerve most commonly travels through the two heads of the SCM muscle,⁷ but could also travel between the two heads of the muscle.¹³ In this region, the nerve merges with fibers from C2 to C4.^{7,14-16} Then, the nerve travels obliquely through the posterior triangle toward the deep cervical fascia and trapezius muscle, staying in a fat layer in between the trapezius and levator scapulae muscles.^{6,13}

The second, third, and sometimes the fourth cervical spinal nerves of the ventral rami also enter the muscle.¹ It is thought that the C2-C4 connections carry sensory (mostly proprioceptive) information.¹ Contrary to this thought, electromyographic^{15,17} and histochemical¹⁷ data show that the nerves have both sensory and motor functions.

Several authors have also demonstrated variations of innervation of this muscle including the hypoglossal nerve,¹⁸ ansa cervicalis,^{19–21} facial nerve,²² and aberrant rami of the transverse cervical nerve.²⁰

Although lesions to the spinal accessory nerve are rare, iatrogenic injury contributes to most of the insults to the spinal accessory nerve. Injury often occurs during radical neck dissection, modified radical neck dissection, or functional neck dissection for the removal of cervical lymph node metastases from head and neck cancer.^{23–27}

The blood supply to the upper portion of the SCM muscle comes from branches of the occipital and posterior auricular arteries. The superior thyroid artery supplies the middle portion of the muscle and the suprascapular artery supplies the lower portion of the muscle.¹

2.2. Function

Both Muscles Bilaterally

The SCM muscles have several important functions while working together bilaterally. When in the upright position with the muscles acting from below, they bring the head forward, assisting the longus colli muscle to flex the cervical spine. When working against gravity, as in the supine position, the muscles work to lift the head up. When the head is fixed, the muscles assist in the elevation of the thorax with forced inspiration.¹

With an upward gaze, the muscles function bilaterally as a checkrein to control hyperextension of the neck. They can also resist forceful backward movement of the head, which can occur when a passenger is riding in a vehicle that is struck from the rear.²⁸

The two SCM muscles are coactivated with mandibular movements such as chewing^{29–32} and swallowing.^{33,34} Coactivation can also contribute to spatial orientation, weight perception, and motor coordination.²⁸

One Muscle Unilaterally

Acting unilaterally, the SCM muscle can side bend the head to the ipsilateral side or rotate the head to the contralateral side. When combined together, these motions allow for an upward sideways glance.¹

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 7-1 grossly

represents the functional unit of the SCM muscle.²⁸

Box 7-1 Functional unit of the sternocleidomastoid muscle

Action	Synergists	Antagonist
Head and cervical spine rotation (contralateral)	Ipsilateral upper trapezius Contralateral splenius capitis Contralateral rectus capitis posterior major Contralateral rectus capitis posterior minor Contralateral obliquus capitis inferior	Contralateral upper trapezius Ipsilateral splenius capitis Ipsilateral rectus capitis posterior major Ipsilateral rectus capitis posterior minor Ipsilateral obliquus capitis inferior
Head and cervical spine side bending (ipsilateral)	Ipsilateral upper trapezius Ipsilateral scalenes Ipsilateral rectus capitis posterior major Ipsilateral rectus capitis posterior minor Ipsilateral obliquus capitis superior	Contralateral upper trapezius Contralateral scalenes Contralateral rectus capitis posterior major/minor Contralateral obliquus capitis superior
Cervical spine flexion	Longus colli Longus capitis Scalenes	Splenii capitis Splenii cervicis Semispinalis capitis Semispinalis cervicis

Together, both SCM muscles are synergistic in controlling hyperextension of the head and neck with a checkrein function. Likewise, they are synergistic with the scalene muscles bilaterally during vigorous chest breathing (inhalation).

Acting with the ipsilateral scalene and trapezius muscles, the SCM helps compensate for the head tilt that is due to tilting of the shoulder girdle axis, which, in turn, is often caused by the functional scoliosis associated with a length discrepancy (LLD), small hemipelvis, and/or quadratus lumborum TrPs (Refer to Chapter 50).

Both SCM muscles are also synergistic to the muscles of mastication (masseter, temporalis, and medial and lateral pterygoid) and the supra- and infrahyoid muscles because they are activated with chewing and swallowing, respectively.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The sternal and clavicular divisions of SCM have their own characteristic referred pain patterns.^{35–38} Face pain referred from TrPs in this muscle is frequently the basis for the diagnoses of “atypical facial neuralgia.”³⁷ Trigger points in this muscle can also be the source of pain and associated symptoms related to the ears, nose, and throat.³⁹

Sternal Division

The sternal division of the SCM muscle can exhibit TrPs in any part of the muscle. Commonly, TrPs found in the lower portion of the sternal division refer pain to the upper portion of the sternum (Figure 7-2A). This presentation is the only downward reference of pain from this muscle.^{35,37} Trigger points in this lower portion have also been seen to contribute to a paroxysmal dry cough.

In the midportion of the sternal division, TrPs refer a deep aching pain ipsilaterally across the cheek (often in finger-like projections) and into the maxilla, over the supraorbital ridge, and deep within the orbit (Figure 7-2A).⁴⁰ They can also refer pain to the pharynx and to the back of the tongue during swallowing⁴¹ (which can be reported as a “sore throat”) as well as to a small round area at the tip of the chin.³⁷ Marbach⁴² shows a similar pattern that includes the cheek, temporomandibular joint, and mastoid areas. Trigger points in this region have also been reported to reproduce the crackling sound in one patient’s ear.²⁸

Figure 7-2. Referred pain patterns (solid red shows essential zones and stippling shows the spillover areas) of the right SCM muscle. A, The sternal (more anterior and more superficial) division. B, The clavicular (more posterior and deeper) division.

In the proximal end of the sternal division, TrPs commonly refer pain to the occipital ridge far behind the ear and to the vertex of the head with scalp tenderness in the pain

reference zone.

Autonomic symptoms of TrPs in the sternal division relate to the ipsilateral eye and nose.^{35,37} Eye symptoms may include excessive lacrimation, reddening of the conjunctiva, apparent “ptosis” (narrowing of the palpebral fissure) with normal pupillary size and reactions, and visual disturbances. This “ptosis” is not caused by weakness of the levator palpebrae muscle, but rather it is due to the spasm of the orbicularis oculi muscle, which is caused by referred increased excitability of the motor units of this muscle. The patient may have to tilt the head backward to look up, because of the inability to raise the upper eyelid. Visual disturbances can include not only blurred vision,^{35,43} but also perceived dimming of light intensity.⁴⁴ Sometimes coryza and maxillary sinus congestion develop on the affected side.

Trigger points in SCM muscle have also been linked with unilateral deafness in a few patients with no associated reports of tinnitus.²⁸ Wyant⁴⁰ attributed tinnitus in one patient to TrPs in either the upper trapezius, or the cervical paraspinal muscles. More recently, Teachey³⁹ has reported similar symptoms of TrPs in the SCM including visual blurring, light sensitivity, reddening of the conjunctiva, tearing of the eyes, and “sinusitis” symptoms.

Clavicular Division

The clavicular division of the SCM muscle can exhibit TrPs in any part of the muscle. Commonly, TrPs in the midfiber part of this division commonly refer pain to the frontal area of the head and when severe, the pain extends across the forehead to the other side,^{35,44} which is very unusual for TrPs. The upper part of this division is likely to refer pain deep into the ipsilateral ear and to the posterior auricular region (Figure 7-2B). Recently, Min et al⁴⁵ reported similar findings of the clavicular head of the SCM muscle referring to the posterior auricular region in a patient. Travell has even reported poorly localized pain to the cheek and molar teeth on the same side with this division of the muscle.³⁷

Trigger points in the clavicular division can also contribute to spatial disorientation.^{43,46} The reported dizziness is more of a sensation within the head, and less often, a true sensation of vertigo.^{43,46} Weeks and Travell⁴⁶ found that during severe attacks, syncope following sudden turning of the head may be due to stretch-stimulation of TrPs in the clavicular division. Episodes of dizziness lasting from seconds to hours are induced by a change of position that require contraction of the SCM muscle, or that places it on a sudden stretch. Disequilibrium may occur separately from, or be associated with, postural dizziness and may cause sudden falls when bending or stooping, or ataxia (unintentional veering to one side while walking with the eyes open).³⁸ Good⁴⁷ attributed symptoms of dizziness to TrPs in either the SCM or the upper trapezius muscles; however, Simons et al²⁸ have only observed this symptom from the former, despite both muscles being commonly involved. More recently, Teachey³⁹ has reported dizziness, hearing loss, hyperacusis, hypoacusis, and the sensation of blocked ears with TrPs in the clavicular

division of the SCM muscle.

Trigger points in the clavicular division can also cause the autonomic phenomena of localized sweating and vasoconstriction (blanching and thermographic cooling) to the frontal area of the head where pain is commonly referred.

3.2. Symptoms

Contrary to expectation, neck pain and stiffness are generally not the most common reports with SCM TrPs,⁴⁸ although this muscle may add an additional component to the “stiff neck” syndrome,⁴⁸ which is primarily due to TrP activity in the levator scapulae, posterior cervical, and trapezius muscles. Trigger points in this muscle may cause tilting of the head to the ipsilateral side, because holding the head upright causes pain.⁴⁹

The patient may report “soreness” in the neck when rubbing these muscles, but the symptom is often mistakenly attributed to lymphadenopathy. Surprisingly, the patient with SCM TrPs prefers to lie on the side of the sore muscle if a pillow is adjusted to support the head, so that the area of referred tenderness in the face does not bear weight.

Sternal Division

Pain referred from the sternal division may occur independently of pain referred from the clavicular division.³⁷ Patients with TrPs in the sternal division can report pain in the cheek, temple, and orbit. Pressure behind the eye is a very common complaint. Patients with cheek pain may seek medical attention for a suspected sinus infection. However, on evaluation, no other signs or symptoms are found to support the diagnosis of “sinus infection.”

The patient may report ipsilateral sweating of the forehead, reddening of the conjunctiva, and tearing of the eye, rhinitis, and apparent “ptosis” (narrowing of the palpebral fissure). Blurred or double vision is sometimes reported, yet the pupils react normally to stimuli. Patients likely report this symptom more when viewing strongly contrasting parallel lines such as Venetian blinds. With the report of visual blurring and light sensitivity patients may be misdiagnosed of suffering migraines, yet the symptoms may arise solely from TrPs in the SCM muscle. Patients with bilateral TrPs may report a persistent dry, tickling cough.

Clavicular Division

Patients with TrPs in the clavicular division of the SCM muscle may report deep pressure and pain, localized sweating, and/or cooling sensations on one or both sides of the frontal region of the head.

Patients may report dizziness with hyperextension of the neck and overstretching of the muscle, for example, when lying without a pillow on a hard examination table, or with turning over in bed at night. During the day, transient loss of equilibrium is likely to follow quick vigorous rotation of the head and neck. During an acute attack of this postural

dizziness, a person suddenly has serious difficulty performing a task at hand. Postural responses are also exaggerated in some patients; when looking up, they feel as if they will “pitch over backward,” and when glancing down, they tend to fall forward. Patients may even report difficulty walking in a straight line across the room.

Nausea is common, but vomiting is infrequent. Dimenhydrinate (Dramamine) may relieve the nausea, but not the dizziness. Patients may even complain of a “sick stomach” with nausea resulting in anorexia that could lead to a poor diet. Reports of seasickness or carsickness could also be related to TrPs in this muscle.

Loss of equilibrium may also follow sustained tilting of the head to one side, as when holding a phone to the ear, or bird-watching with binoculars. The disturbed proprioception causing postural dizziness may be more disabling than the head pain coming from this muscle. These symptoms may appear in any combination, or all can appear together.

It has been reported in a few patients that hearing was impaired unilaterally. Although less common, tinnitus can originate from TrPs in the SCM muscle, but is more likely to originate in TrPs of the deep division of the masseter muscle.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper assessment and examination of the SCM muscle, the clinician should assess head and neck posture, range of motion, and joint accessory motion of the occiput-C1 and C1-C2 segments. Testing of the C1-C2 segment should be assessed with locking of the mid and lower cervical spine in side bending and then rotating the head on the neck in the side-bent position. Many times “restrictions” of this segment are normalized with the treatment of the SCM muscle. Observation of posture typically reveals a forward head position with an extended upper cervical spine, and a flexed lower cervical spine. A lateral tilt of the head may also be observed. A patient with headache primarily due to SCM TrPs has minimal restriction of the active range of head and neck motion. Active flexion may be slightly restricted as noted by the lack of about one fingerbreadth distance between the chin and the sternum.

When examining the patient with SCM TrPs in standing, one may observe a leg length discrepancy. If the discrepancy is less than 6 mm (0.25 in), the shoulder opposite to the short leg usually sags, whereas in a patient with 1.2 cm (0.5 in) or more of leg length discrepancy, the shoulder is more likely to droop on the same side as the short leg.^{28,50}

The patient with dizziness and disequilibrium due to TrPs in the clavicular division typically has a negative Romberg sign and nystagmus. With myofascial disequilibrium, the patient cannot walk in a straight line toward a point across the room where he or she fixes the gaze. The patient’s path instead veers to one side, usually to the side of active TrPs in the clavicular division. With any symptoms related to dizziness or disequilibrium, a thorough examination of the vestibular system should be performed to rule out other

potential disorders. Refer to other sources for a thorough examination of the vestibular system.

When objects of equal weight are placed in the hands of a patient with unilateral TrPs of the clavicular division, an abnormal Weight Test may be positive.²⁸ When asked to determine which of the two objects is heavier, the patient demonstrates baragnosia by underestimating the weight of the object held in the hand on the same side as the affected SCM muscle. If TrPs are present bilaterally, the baragnosia is difficult to observe.

3.4. Trigger Point Examination

Currently, there are no reliability studies specific to the examination of the SCM muscle for TrPs; however, in other muscles Gerwin et al⁵¹ found that the most reliable examination criteria for making the diagnosis of TrPs were the identification of a taut band by palpation, the presence of spot tenderness in the band, the presence of referred pain, and reproduction of the patient's symptomatic pain. Although identification of a local twitch response by palpation was unreliable, it is a valuable objective confirmatory finding when present.

Figure 7-3. Examination of the SCM muscle is most effective using pincer palpation for both divisions and may be done with the patient supine or seated. A, Examination of the deeper clavicular division, with the patient supine and the head tilted toward the same side to slacken the muscle and permit the clinician's fingers to reach between it and underlying structures. B, Examination of the lower end of the sternal division, with the patient seated.

For examination of the SCM muscle, a cross-fiber pincer palpation is utilized with the muscle held between the thumb and the fingers, separating it from the underlying structures in the neck. The patient is positioned supine, preferably (Figure 7-3A), or may

be seated (Figure 7-3B). Supine position is the most effective because the muscle is more relaxed. The muscle is slackened somewhat by tilting the patient's head toward the ipsilateral shoulder on the symptomatic side (Figure 7-3B) and, if necessary, by turning the face slightly away from the muscle to be examined. Snapping a band between the fingers at the TrP regularly produces a visible twitch response, which may be seen as a slight jerk of the head. The entire muscle should be examined for TrPs because TrPs may lie close to the upper or lower attachments, or at the midlevel of either division. Both divisions should be examined thoroughly. Trigger points close to the proximal and distal ends of this muscle may be more effectively examined using a cross-fiber flat palpation.

Figure 7-4. A, Undesirable head and neck position with head turned to one side and arms unsupported. This can activate and perpetuate TrPs due to sustained contraction and overload, particularly in the uppermost portion of the SCM muscle. B, Desirable head and neck position for reading in bed with arms supported and head forward.

A prickling sensation over the mandible, which is the characteristic referred response of TrPs in the overlying platysma muscle, may inadvertently be triggered while palpating the SCM muscle. This may startle and concern the patient, especially if this unexpected sensation is not explained.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the SCM muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁵² Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. For instance, maintaining a position of protracted neck extension places a significant amount of strain on the muscles, for example, painting a ceiling, hanging curtains, and sitting in a front-row seat in a theater with a high stage.

Paradoxical breathing, a chronic cough, emphysema, or asthma (COPD), can chronically overload this accessory muscle of respiration. An acute cough due to upper

respiratory infection can activate SCM TrPs and cause an intense headache with every coughing spell.

Patients may acutely overstress the SCM muscles with the hauling and pulling associated with horseback riding, the handling of horses, and moving heavy equipment or furniture.

Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. Reading in bed with your head turned to one side (Figure 7-4A) can activate and perpetuate SCM TrPs, because the muscle on one side is in a shortened position and the other side is in a lengthened position. This is corrected by placing the head and neck in a neutral supported position (Figure 7-4B). Similarly, cocking or tilting the head to avoid the reflection of overhead lights from corrective eyewear,³⁵ to accommodate for a short cord on a handheld electronic device, or to improve hearing in one-ear deafness, can stress the SCM muscle in some patients. Other postures that are problematic due to keeping the muscle in a shortened position include excessive forward head posture; sitting with the head turned to the side for prolonged periods, for example, when watching television or while talking to another person; or sleeping on too many pillows to improve “sinus drainage.” If the head should have to be elevated, it is advisable to use a wedge under the upper trunk and head, rather than to use extra pillows to only raise the head.

Another problem is a structural inadequacy, such as a leg length discrepancy or small hemipelvis, both of which produce a functional scoliosis and shoulder girdle tilting. The SCM muscles, in conjunction with the scalene muscles, are easily overloaded by maintaining normal head position to level the eyes in compensation for a tilted shoulder girdle axis.

The SCM muscle can be affected by anything that produces a severe deviation from the normal pattern of gait. Limping on a weight-bearing limb (with resultant torso adjustments) and lack of normal push-off at the end of the stance phase can activate TrPs in the SCM (and levator scapulae and scalene muscles), because those muscles contract excessively in their reflex attempt to “help the movement” and/or maintain equilibrium.

Sternocleidomastoid TrPs can be also be activated and/or perpetuated by a tight clavicular head of the pectoralis major muscle, pulling down and forward on the clavicle, thereby placing tension on the clavicular head of the SCM muscle.

The leakage of cerebrospinal fluid, which occasionally follows a spinal tap or myelogram, may cause irritation of brain stem structures and activate SCM TrPs.⁵³ These TrPs may then persist and cause chronic headache for weeks, months, or years, which, regardless of the duration, can be relieved by inactivating the responsible myofascial TrPs.

Finally, sudden trauma, such as sustaining a whiplash from an auto accident,^{54,55} falling off a horse, or falling down steps can also contribute to TrP activation.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.⁵⁶ Therefore,

musculature in the referred pain areas for each muscle should also be considered. Muscles in the referred pain regions of the SCM muscle include the masseter, temporalis, orbicularis oculi, and occipitofrontalis muscles. These muscles, as well as a painful temporomandibular joint, may not respond to treatment completely until the SCM muscle is effectively released. Hong⁵⁷ demonstrated that SCM TrPs can contribute to the development of associated TrPs in the temporalis, masseter, and digastric muscles, and that inactivation of the SCM TrP inactivated its associated TrPs without any further treatment of them.

Commonly, when TrPs are present in one SCM muscle, they are usually found in the opposite muscle as well. The scalene muscles also tend to develop TrPs, especially if the SCM muscle has been affected for an extended period of time. If the neck rotation is “stiff,” TrPs may be present in the levator scapulae, trapezius, splenius cervicis, and other posterior neck muscles.⁴⁸

The sternalis muscle may also develop associated TrPs as a result of TrPs in the lower portion of the sternal division of the SCM muscle. Sternalis TrPs refer pain deep under the sternum and across the upper pectoral region to the arm on the same side (refer to Chapter 43). As a result of this referral pattern, the pectoral muscles may then develop associated TrPs.

Finally, the platysma muscle, a thin muscle that overlies the SCM muscle, may develop TrPs in relation to involvement of the SCM muscle.

4.3. Associated Pathology

Trigger points in this muscle are associated with or can mimic many different conditions; therefore, a thorough medical screening and examination are essential and a possible referral to another healthcare practitioner may be necessary.

Migraines,⁵⁸ tension-type headaches,^{59–61} cervicogenic headaches,^{62–64} temporomandibular dysfunction,⁶⁵ whiplash-associated disorder,^{54,55} and mechanical neck pain⁶⁶ are all associated with TrPs in the SCM muscle.

Vertigo should be distinguished from postural dizziness; the latter is a nonspecific feeling of disorientation, reported by some patients as a “swimming in the head” sensation. The patient’s imbalance and spatial disorientation due to myofascial TrPs may mimic ataxia.

Dizziness from conditions such as benign paroxysmal positional vertigo (BPPV) and Ménière disease should be ruled out. BPPV is a problem of the inner ear that is associated with nystagmus and vertigo while moving the head in specific directions, which depends on the canal involved. Clinical tests to help aid in the diagnosis include the Dix-Hallpike, and supine head roll test.⁶⁷

Unlike Ménière disease, symptoms and signs arising from TrPs in the clavicular division are rarely associated with unilateral deafness. Vestibular evaluation reveals a normal calorimetric test, a negative Romberg sign, normal pupillary response, no nystagmus, and no neurologic deficit. Consciousness is unimpaired. These features distinguish the myofascial syndromes from more serious conditions such as trigeminal neuralgia, Ménière

disease, cerebellopontine tumors, intracranial vascular lesions, inflammation of the labyrinth, hemorrhage into the pons, and petit mal epilepsy.²⁸

Dizziness due to vestibular disease is identified by nystagmus and other tests of vestibular function as described above. The nonvestibular sources of dizziness include ear wax that touches the tympanic membrane; stenosis of the internal carotid artery, which may be detected by listening for a bruit over the bifurcation of the carotid artery or higher in the neck; hypertension; or intracranial aneurysm or tumor.

The pain from SCM TrPs can mimic true trigeminal neuralgia in distribution; however, the pain is described quite differently. First, the pain of trigeminal neuralgia is typically described as “shock-like.” According to the International Headache Society,⁶⁸ the criteria for this diagnosis include at least three attacks of unilateral facial pain that meet the following criteria: (1) occurring in one or more divisions of the trigeminal nerve, with no radiation beyond the trigeminal distribution and (2) pain with at least three of the following four characteristics: (a) recurring pain in paroxysmal attacks lasting from a fraction of a second to 2 minutes; (b) severe intensity; (c) electric shock-like, shooting, stabbing, or sharp in quality; and (d) precipitated by innocuous stimuli to the affected side of the face. The facial grimace of trigeminal neuralgia clearly distinguishes this neurologic disease from atypical facial neuralgia and from pain due to TrPs in the sternal division of the SCM muscle.³⁷

Trigger point involvement of the SCM, splenii capitis and cervicis, levator scapulae, and upper trapezius muscles should be distinguished from spasmodic torticollis (cervical dystonia), which is a neurologic condition characterized by involuntary dystonic movements of the head^{69,70} that can be genetic, acquired, or idiopathic.⁷¹ The muscles most commonly involved in this condition include the SCM, trapezius, scalenes, and platysma muscles,⁷² making the differential diagnosis of this condition (versus TrPs) essential to ensure proper care. With spasmodic torticollis, hypertrophy of the muscles may develop.⁶⁹ In contrast, the apparent shortening of a muscle due to TrPs does not cause hypertrophy, nor does it cause involuntary movements of the head. Although physical therapy interventions can be effective for spasmodic torticollis,^{73,74} botulinum toxin is the preferred treatment.^{70,75–78}

Ocular torticollis may result in abnormal head positions to optimize visual acuity and maintain binocularity. In many of these ocular muscle conditions the patient presents in a chin up head position. With ocular muscle palsy's, the head usually tilts to the weak side and turns toward the uninvolved side, representing a functional torticollis.⁷⁹

When the spinal accessory nerve (cranial nerve XI) penetrates the SCM muscle en route to the trapezius muscle, myogenic torticollis due to contracture of the SCM muscle can cause paresis of the ipsilateral trapezius muscle.⁸⁰

Any local areas of chronic infection such as sinusitis or a dental abscess should be identified and resolved. Herpes simplex (oral) recurrent infection may be a stubborn perpetuator of TrPs in the neck and the masticatory muscles.

When autonomic symptoms are due to myofascial TrPs in the sternal division, the

absence of miosis and enophthalmos, and the presence of a ciliospinal reflex rule out a Horner syndrome.⁸¹ The eye symptoms should also be distinguished from paralysis of the extraocular muscles.

For further discussion on the differential diagnosis of “stiff neck” of myofascial origin,⁴⁸ refer to Chapter 18.

Intramuscular hemangiomas (IH) are rare benign vascular neoplasms, especially uncommon in the SCM muscle, but important to recognize.⁸² They typically present as a localized, palpable mass with distinct edges and a rubbery consistency. Pain may or may not be present, but when present, it is due to nerve compression. Commonly, pulsations and bruits are absent.⁸²

5. CORRECTIVE ACTIONS

An effective ergonomic workstation is essential for anyone who spends time at a desk with a computer. It is important to learn how to keep joints in a neutral position when possible, and to minimize excessive twisting and turning movements or prolonged positions with the head turned. For a lasting relief, mechanical perpetuating factors such as forward head posture and rounded shoulder posture should be corrected (see Chapter 76).

Patients who are intensely preoccupied with what they are doing are susceptible to lose track of time and maintain an undesirable posture. This can happen while engrossed at a computer or leaning forward over a desk for a prolonged period while writing. Trigger points have been shown to develop with 1 hour of typing.⁸³ Patients can relieve muscle tension every 20 or 30 minutes, without significantly interrupting work, by setting an interval-timer for that length of time and placing it across the room. Then, they should get up and stretch while they walk to turn off the buzzer and reset the timer. Computer or phone timers may also be used as effective tools for break reminders. Muscles are more tolerant of prolonged activity if they have frequent short breaks permitting relaxation. A few cycles of active range of motion makes the break more effective. For the SCM muscle, this is achieved by slowly rotating or side bending the head to the right and then the left.

A person with SCM TrPs should not sit with the body facing in one direction while looking in another direction for a prolonged period because this rotation leads to neck muscle problems. For example, when one needs to direct attention toward another person for an extended conversation or toward the television set for a prolonged time, either the chair or the person’s body should be turned, not just the head.

When turning over in bed at night, the patient should roll the head on the pillow, not lift the head. When getting out of bed in the morning, the patient should roll onto one side and swing the legs off the bed to sit up instead of pulling the trunk straight up because this action places additional strain on the SCM muscles.

During nighttime sleep, because of the increased firmness and recoil, foam pillows tend to be more uncomfortable than softer pillows for patients with SCM TrPs. Pillows should not be placed under the shoulder, but instead behind the neck to allow for proper support. Depending on the amount of kyphosis a patient has and the thickness of his or her pillows,

1 to 2 pillows should be appropriate. In a supine position, proper thickness does not allow any extension of the head, but also does not place the head in excessive flexion, causes prolonged lengthening or shortening of the anterior neck muscles, respectively, during sleep. A small towel roll can be placed inside the pillowcase to support the neck in a neutral position, thus placing the face parallel to the bed. The patient can tuck the corner of the side pillow between the shoulder and the chin (Figure 7-5A), but NOT under the shoulder. For sleeping on the side, the pillow should be thick enough to keep the head and neck in a neutral position, so that the head is not bent excessively to either side because this causes excessive lengthening of the muscle on the top side and excessive shortening of the muscle on the pillow side. The patient can tuck the corner of the pillow between the shoulder and the chin in side-lying position as well (Figure 7-5B), but not under the shoulder. It is recommended to avoid sleeping prone due to the excessive shorting of the muscle on one side and excessive lengthening of the muscle on the other side. If one does sleep prone, a pillow placed under the shoulder and chest on the same side to which the face is turned helps reduce rotation of the neck. A semiprone position can also be utilized, achieved by flexing the knee and hip of the side toward which the face is turned, which helps by partly rotating the torso (Figure 7-5C).

Figure 7-5. A, Correct position, patient supine with the corners of the pillow tucked between the chin and shoulders. B, Correct position, patient side lying, with the pillow between the head and shoulder. C, Effective position for stomach sleepers to decrease stress on the SCM muscle.

If reading in bed, the light should be located directly overhead, on the headboard, on the wall, or suspended from the ceiling. It should not illuminate only one side of the bed because this placement can place excessive strain on the SCM muscles, if the head is turned to maximize the light cast on reading material.

When using a phone, it should not be held between the head and the shoulder by tilting the head. Instead, a headset, headphones, or hands-free speaker function should be utilized.

An LLD or a small hemipelvis that tilts the shoulder girdle axis should be corrected by suitable lifts.

Pressure on the SCM muscles and activation of TrPs may be caused by tightness of a shirt collar. The clinician's finger should fit comfortably inside the collar, not only when the patient is looking straight ahead, but also when the head is turned, which increases the diameter of the neck inside the collar. Tying a necktie too tightly should be avoided.

To stretch the SCM muscle, the patient rotates the head toward the affected side and gently assists retraction of the head with two fingers of the opposite hand (Figure 7-6). This motion is also a good self-mobilization technique for the C1-C2 segment that is often found to be restricted in patients with SCM TrPs.

Missaghi⁸⁴ described a passive stretch technique that can improve symptoms associated with SCM TrPs when incorporated into a home program. In the supine position, the patient side bends the head toward the affected side, rotates the head away from the affected side, and then performs a chin tuck with cervical extension. This position is held for 5 to 45 seconds.

Lewit⁵⁰ illustrated and described a gravity-induced postisometric relaxation technique suitable for a home program for release of TrPs in the clavicular division of the SCM muscle. The supine patient rests the head at the edge of the bed and turns the face to one side, chin supported by the edge of the supporting surface acting as a fulcrum. The patient looks up with the eyes only, and takes in a slow, deep breath using diaphragmatic (abdominal) breathing. This effort lightly activates the uppermost SCM muscle. During slow exhalation, the patient looks down and relaxes, allowing the head to drop slightly, elongating the SCM muscle with each breath (Figure 7-7).

Figure 7-6. Stretching of the right SCM muscle in sitting. The patient rotates the head toward the side to be stretched. From this rotated position, the opposite hand (two fingers) is placed on the chin guiding the head and neck to retract, creating a gentle stretch along the SCM muscle.

Figure 7-7. Postisometric relaxation for SCM muscle. The supine patient rests the head at the edge of the bed and turns the face to one side, chin supported by the edge of the supporting surface acting as a fulcrum. The patient looks up with the eyes only, and takes in a slow, deep breath using diaphragmatic (abdominal) breathing. This effort lightly activates the uppermost SCM muscle. During slow exhalation, the patient looks down and relaxes, allowing the head to drop slightly, elongating the SCM muscle with each breath.

Because a tight clavicular head of the pectoralis major muscle can influence the SCM muscle, this muscle might also need to be addressed. Refer to Chapter 42, Figure 42-10, for a procedure on stretching of this muscle. It should be noted that while performing this stretch, the patient should not protrude the head forward or look down because this shortens the SCM muscles.

Proper diaphragmatic breathing should be established in all patients with SCM TrPs because this muscle is an accessory muscle of respiration. If proper breathing is not established, the SCM muscle can be overutilized, which can further perpetuate TrPs. For those who have asthma, allergies, or other respiratory conditions, this strategy is even more important. Proper pharmacologic management of respiratory symptoms related to these conditions should be encouraged as well.

Masseter Muscle

“Dental Drama”

Seth Jason Fibraio and Michelle Finnegan

1. INTRODUCTION

The masseter muscle is one of the most common muscles involved with patients who have temporomandibular dysfunction (TMD) and oftentimes it restricts jaw opening. The muscle is comprised of three layers. The superficial and intermediate layers attach proximally to the anterior two-thirds of the zygomatic arch. The superficial layer inserts distally to the lower posterior half of the mandibular ramus. The middle layer of the muscle attaches to the central part of the ramus of the mandible. The deep layer of the masseter muscle attaches to the posterior one-third of the zygomatic arch and inserts distally to the lateral surface of the coronoid process of the mandible. The masseter muscle is innervated by the masseteric nerve and receives its vascularization from the masseteric branch of the maxillary artery, the transverse branch of the superficial temporal artery, and the facial artery. The primary function of the masseter muscle is mandibular elevation and it plays a small role in ipsilateral lateral excursion, protrusion, and retraction of the mandible. Trigger points (TrPs) in the masseter muscle commonly refer pain in the middle third of the zygomatic arch superiorly, to the lateral aspect of the mandible inferiorly and to the lateral aspect of the forehead. Symptoms are exacerbated with mouth opening, chewing, and lying on the affected side. Perpetuating factors include static activities such as clenching, dynamic activities such as nocturnal bruxism, and stretching activities such as yawning. Trigger points in the masseter muscle are associated with tension-type headaches (TTH), TMD, and unilateral tinnitus. Differential diagnosis should include screening to rule out TMD, trigeminal neuralgia, masseter hypertrophy, and/or neoplasms. Corrective actions for this muscle include maintaining an effective rest position of the tongue, correction of forward head posture, reducing/eliminating parafunctional behaviors, stress management, and self-release of the muscle, either intraorally or extraorally.

2. ANATOMIC CONSIDERATIONS

The masseter muscle is a pennate-shaped muscle, with thick aponeurotic layers. It is comprised of three layers, superficial, middle, and deep, which aide in creating a great amount of force needed for mastication. The superficial and intermediate portions of the masseter muscle are considered together as the superficial layer of the muscle, because they both attach proximally to the anterior two-thirds of the zygomatic arch and have a similar fiber direction. The superficial layer is the largest. Distally, the superficial layer attaches to the lower posterior half of the mandibular ramus externally (Figure 8-1). The middle layer of the masseter muscle attaches into the central part of the ramus of the mandible. The deep masseter muscle attaches proximally to the posterior one-third of the zygomatic arch and attaches distally to the lateral surface of the coronoid process of the mandible and to the superior half of the ramus (Figure 8-1).^{1, 2} This attachment may extend to the angle of the mandible.¹ There is debate on whether there are fibers that attach to the articular disc of the temporomandibular joint and whether it can influence the disc.^{1, 3} The deep fibers run more vertically than the superficial fibers and the most posterior of the deep fibers are considerably shorter than those in the rest of the muscle.⁴

Figure 8-1. Masseter muscle attachments are from the maxillary process of the zygomatic

bone and the anterior two-thirds of the inferior border of the zygomatic arch.

The proximal tendon of the masseter muscle is referred to as a “tendinous digitation,” which is longer and wider in men than in women, with men having three digitations and women having two. Fewer digitations lead to decreased bite force production in women as compared with that in men.⁵ The thickness of the masseter muscle ranges from a relaxed thickness of 12.1 ± 1.4 mm to a contracted thickness of 14.2 ± 1.7 mm.⁶

In one study,⁷ the anterior fibers of the masseter muscle (both superficial and deep) were nearly 87% type-I (slow twitch) fibers and nearly 7% type-II-B (fast twitch) fibers. The posterior muscle fibers were also predominantly type-I fibers (70% superficial and 77% deep), but the posterior portion had more type-II-B fibers (20% superficial and 15% deep) than the anterior portion. The large amount of type-I fibers facilitate fine control as the molar teeth approach occlusion during chewing.⁷ A more recent study revealed a different composition of muscle fiber types. Rowlerson et al⁸ suggest that the normal distribution of fibers is: Type-I fibers ~50%, Type-II fibers ~15% (smaller than normal diameter), Type-I/II hybrid fibers 20%, and neo-atrial fibers ~15%. Compared with most limb and trunk muscles, this is an unusually high proportion of slow twitch fibers, which indicates that the muscle is suited primarily for sustained workloads with few brief rapid adjustments. Patients with TMD tend to have an increased number of type-II fibers.^{8,9} The number of intrafusal fibers per muscle spindle was found to be unusually high in this muscle (up to 36).¹⁰ This finding supports the understanding that masseter muscle spindles have a strong proprioceptive influence on fine control of jaw closure.

2.1. Innervation and Vascularization

The masseter muscle is innervated by the masseteric nerve that arises from the anterior branch of the mandibular division of the trigeminal nerve (cranial nerve V).¹ The mandibular nerve descends through the foramen ovale into the infratemporal fossa proximally to the lateral pterygoid. The mandibular nerve is divided into a posterior and an anterior trunk. The anterior trunk contains the buccal, masseteric, and anterior deep temporal nerves. The masseteric nerve then passes laterally to the lateral pterygoid muscle near the base of the skull, then crosses the mandibular coronoid notch where it innervates the masseter muscle.¹¹ The masseteric nerve and artery travel together, with the nerve having 3 to 7 separate innervations to the superficial and deep portions of the masseter muscle.⁵

The vascular supply to the masseter muscle is via the masseteric branch of the maxillary artery, the transverse branch of the superficial temporal artery, and the facial artery.¹ The masseteric branch of the premasseteric artery, the masseteric branch of the transverse facial artery, the masseteric branch of the external carotid artery, and a muscular branch of the deep temporal artery have also been reported to supply blood to the masseter muscle.¹² The maxillary vein emerges between the masseter muscle and the mandible, causing it to be potentially entrapped by masseter TrPs. The pterygoid venous plexus, which empties

primarily into the maxillary vein, lies between the temporalis and the lateral pterygoid muscles and between the two pterygoid muscles; the plexus drains the temporalis muscle via the deep temporal vein and drains the infraorbital region via the orbital vein.¹

2.2. Function

The primary action of the masseter muscle is to elevate the mandible and close the jaw during clenching into centric occlusion.^{1,13-16} The deep fibers also retract the mandible.^{1,13} There is a small contribution of this muscle to lateral excursion without bite force.¹⁷ Interestingly, clenching during left and right lateral excursion, results in a decrease in the electromyographic (EMG) activity of the masseter and temporalis muscles bilaterally.¹⁸

The masseter muscle contributes to the morphologic role of lower face contour (facial height and mandible size)¹⁹ and functions in the biting down of food, drinking, swallowing, and speaking and nonfunctional activities such as clenching and grinding.^{20,21} Normally, activity of the masseter muscle is not required to maintain the mandibular rest position (centric relation).¹³

With mouth opening and closing, it has been observed that simultaneous head flexion and extension occurs.²² When the mouth opens, the cranium rotates posteriorly. During mouth closing (mandibular elevation), the cranium rotates anteriorly. This demonstrates a functional relationship between the trigeminal and craniocervical systems. Any disruption in normal mechanics in either system may alter movement patterns in the other system and increase risk for development of musculoskeletal pain in the head, neck, and jaw.²³

The masseter muscle responds before the temporalis muscle during chewing²⁴ and is typically more active than the temporalis muscle.²⁵⁻²⁷ Patients with TMD had asymmetry in the temporalis and masseter muscles during standard activity when compared with controls, with a greater amount of difficulty chewing hard foods.²⁸

As long as the mandibular rest position is maintained, the masseter muscle showed little difference in electrical activity between sitting and supine postures.²⁹ Valdes et al³⁰ demonstrated no significant difference in EMG activity in the temporal and masseter muscles with the tongue elevated to the roof of the mouth or with the tongue on the floor of the mouth, but vertical dimension did increase with the tongue placed on the floor of the mouth.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs

that may develop in muscles that are functionally interdependent. Box 8-1 grossly represents the functional unit of the masseter muscle.³¹

Box 8-1 Functional unit of the masseter muscle^{13, 15, 32–36}

Action	Synergists	Antagonist
Mandibular elevation	Contralateral masseter Temporalis (bilateral) Medial pterygoid (bilateral)	Lateral pterygoid (inferior division) Geniohyoid Digastric Mylohyoid
Mandibular retraction	Temporalis (posterior fibers more than anterior)	Medial pterygoid Lateral pterygoid Temporalis

The masseter and temporalis muscles function together closely, with only minor differences in motor unit activity. The temporalis muscle is more likely to respond for mandibular balance and posture control, where the masseter muscle is used for greater closing force.³²

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The masseter muscle is one of the most commonly involved muscles in patients with TMD,³³ and it has been found to be the most common muscle to elicit referred pain,³⁴ Fernández de Las Peñas et al³⁵ demonstrated that this muscle reproduces patients' familiar TMJ-related pain. In addition, referred pain from the masseter muscle indicates a 3-times greater risk for the presence of temporomandibular arthralgia.³⁶ Other conditions in which masseter TrPs play a contributing role include tension-type headache^{37, 38} and mechanical neck pain,³⁹ especially if TrPs in neck muscles contribute to the pain.^{40, 41}

Superficial Layer

Trigger points in the superficial layer of the masseter muscle commonly refer pain to the lower jaw, molar teeth, related gums, and the middle one-third of the zygomatic arch of the maxilla.^{33, 34, 42, 43} In addition to referring pain to the upper and lower teeth, TrPs in the superficial masseter muscle can also refer to the ear.³⁵ Oftentimes TrPs in the anterior border and superior part of this layer refer pain to the upper premolar⁴⁴ and molar teeth, adjacent gums, and maxilla (Figure 8-2A).^{42, 45} Trigger points located just below the midbelly of the muscle commonly refer pain to the lower molar teeth and mandible (Figure

8-2B).^{33, 42, 46, 47} Trigger points close to the angle of the mandible frequently refer pain in an arc that extends across the temple and over the eyebrow, as well to the lower jaw (Figure 8-2C).^{48, 33, 39, 42, 43} Kellgren⁴⁸ experimentally induced referred pain from the masseter muscle in a normal subject by injecting 0.1 mL of 6% saline solution into its fibers just above the angle of the mandible. This procedure caused “toothache” of the upper jaw, pain in the region of the TMJ, and pain in the external auditory meatus.

Figure 8-2. Referred pain patterns arising from TrPs in the masseter muscle. Solid red shows essential referred pain zones, and the stippled areas are spillover pain zones. A, Referral patterns from TrPs near the musculotendinous junction of the superficial layer, upper portion. B, Referral patterns from TrPs in midmuscle of the superficial layer. C, Referral patterns from TrPs of the lowest portion of the superficial layer, near its attachment. D, Referral patterns from TrP in the upper posterior part of the deep layer below the temporomandibular joint.

Similar to TrPs in the temporalis muscle, masseter TrPs may also cause tooth hypersensitivity to any or all stimuli, including occlusal pressure, percussion, heat, and

cold.⁴⁷

Deep Layer

Trigger points in the underlying deep layer of the masseter muscle, over the ramus of the mandible, are likely to refer pain diffusely to the midcheek area in the region of the lateral pterygoid muscle and sometimes in the region of the TMJ. Oftentimes, TrPs close to the posterior zygomatic attachment of the deep portion of the masseter muscle refer pain deep into the ear (Figure 8-2D).^{34, 42, 49–52} The deep layer may also cause tinnitus of the ipsilateral ear.^{42, 53} The tinnitus may be constant or may be set off by pressure on the TrP, even though the patient may be unaware of its presence, and therefore its link to his or her symptoms, until the TrP is deactivated.^{42, 54} A study by Saldanha et al⁵⁵ showed an association between TMD and subjective tinnitus with the masseter and anterior temporalis muscles having a lower pain pressure threshold compared with controls.

3.2. Symptoms

Patients with TrPs in the superficial layer of the masseter muscle often report pain in the zygomatic region as a “sinusitis.” Frequently, patients seek medical care thinking they are sick, yet no other findings can confirm the patient is ill.

Similar to the temporalis muscle, pain referred to a tooth by superficial masseter TrPs can easily be misinterpreted as being of endodontic origin.⁴⁴ Patients go to the dentist thinking they have a cavity or some other tooth-related problem. Regrettably, at times, patients have had significant dental procedures for the “tooth” pain, only to find out the problem persists because it was actually nonodontogenic.⁴⁷

If tinnitus is present, patients might notice that stretching the jaw wide open may either activate or interrupt the tinnitus. The tinnitus is usually described as “low roaring” and is not associated with the deafness and vertigo that is common with a vestibular or central neurologic lesion. They may also report that applying pressure to the masseter muscle alters tinnitus.⁵⁴

With TrPs in either or both layers of the masseter muscle, patients can report difficulty with full mouth opening.⁵⁶ It has also been seen clinically that TrPs can contribute to closing of the mandible in a quick, almost snapping-like, motion instead of a controlled movement.

In addition, TrPs in the masseter muscle might restrict venous flow from the infraorbital subcutaneous tissues. This engorgement of the orbital vein produces puffiness (“bags”) beneath the eye on the affected side, and thus narrows the palpebral fissure. Narrowing of the fissure may also be caused by associated TrPs in the orbicularis oculi muscle, which lies in the pain reference zone of TrPs in the sternal division of the sternocleidomastoid muscle.

3.3. Patient Examination

The clinician should be aware that TrPs not only contribute to pain, but also decrease the jaw range of motion. Ipsilateral masseter myofascial pain has been correlated with the presence of TMD.³⁶ Before beginning the physical examination, the clinician should take a thorough patient history. After establishing the history of the condition, the clinician should create a detailed diagram representing the pain described by the patient.

A unilateral dysfunction, whether due to muscle problems or internal derangement of a TMJ, also has an effect on the contralateral side because the mandible spans the midline and attaches to both sides of the cranium. As a result, assessment should always include a bilateral visual and palpatory examination for musculoskeletal dysfunction.

The clinician should check specifically for forward head posture (loss of sternal/malar positioning). Although the relationship between TMD and head posture is somewhat controversial and unclear,⁵⁷ it is thought that forward head posture indirectly induces tension in the hyoid muscles, which in turn pulls downward to create light tensile forces on the mandible.⁵⁸ As a result, this causes the mandibular elevator muscles, such as the masseter muscle, to work harder, to contract to keep the mouth closed.

Masseter TrPs, whether unilateral or bilateral, may cause restriction of mouth opening,⁵⁶ which is evident on examination, although the patient may not be aware of it. Unilateral masseter TrPs tend to deviate the mandible toward the affected side, a deviation that is apparent when the patient slowly opens and closes the mouth. This should be differentiated from a unilateral TMJ internal derangement, which may also cause the mandible to deviate toward the affected side. Of course, with a history of painful joint derangement (localized TMJ pain, + joint sounds), both factors may be present and ultimately need treatment.

A convenient way to estimate interincisal opening that is adjusted to the size of the individual is with the “two-knuckle test” (see Figure 8-3A). Together, the first two knuckles (proximal interphalangeal joints of the second and third digits) should easily fit between the upper and lower incisor teeth. A more critical test is the insertion of a tier of the distal phalanges (not knuckles) of the first three fingers placed between the incisor teeth (Figure 8-3B). This was easily accomplished in an asymptomatic population of patients who were unscreened for masticatory symptoms and/or tender masticatory muscles.⁵⁹

Figure 8-3. A, Two-knuckle test. B, Tiered three-finger test.

Individuals with TrPs in the mandibular elevator muscles are very unlikely to pass the more rigorous “three-knuckle test,” which was first reported by Dorrance⁶⁰ in 1929. This test was found to be a reliable method in a follow-up study in 2008.⁶¹ The patient places the first three knuckles (second, third, and fourth digits) of the nondominant hand between the upper and lower incisor teeth. This test is more demanding than the loose two-knuckle test and requires a degree of forcing for many individuals even when no TrPs are present. This forcing would be unwise for individuals who might have an internal derangement of the TMJ. If the three-knuckle test can be accomplished without forcing, the subject is very unlikely to have masseter (or temporalis) TrPs or significant TMJ dysfunction, but they could have a hypermobile joint.

A more standardized, objective way to measure mouth opening is with a vertical ruler to measure the distance between the upper and lower incisors.^{62, 63} Normal mouth opening for women is 41 to 45 mm and men is 43 to 45 mm.^{64, 65}

3.4. Trigger Point Examination

Among the masticatory muscles, the masseter muscle frequently has TrPs. In one study of 56 patients with myofascial pain dysfunction syndrome as defined by Laskin,⁶⁶ the superficial portion of the masseter muscle was the most commonly involved muscle, and the deep masseter muscle was the fifth most commonly involved.⁶⁷ In patients with temporomandibular arthralgia, 61.6% presented with pain from at least one masseter muscle.³⁶ In another study of 277 similar patients Greene et al,⁶⁸ 81% reported pain. Of these patients with pain, the masseter muscle was the second most commonly involved muscle in regard to tenderness. Sharav and colleagues⁶⁹ observed that the masseter muscle had the second highest prevalence of active TrPs (69%) of 42 patients with the myofascial pain dysfunction syndrome. Solberg et al⁷⁰ noted tenderness in the superficial masseter muscle with limited mouth opening 4 times as often in subjects who reported awareness of bruxism as in those who denied awareness of it. Alonso-Blanco et al³³ found active TrPs of the masseter muscle in 14 out of 20 female patients with fibromyalgia and myofascial TMD.

The entire masseter muscle should be palpated to assess for TrPs. Most of the midbelly of the masseter muscle can be examined for TrPs effectively with a cross-fiber pincer palpation between one digit inside the cheek and another on the outside (see Figure 8-4A). The patient can be in the seated position or, more preferably, in the supine position to ensure adequate relaxation of the patient. Only a thin layer of mucosa separates the palpating finger and the midportion of the muscle. If the clinician has difficulty localizing the muscle itself, he can ask the patient to bite down gently so that he can confirm being on the muscle. Then, with the muscle relaxed, taut bands can be identified by rubbing the muscle fibers between the fingers. The tenderness of the TrP is increased if the patient opens the mouth far enough to take up most of the slack in the muscle (usually the width of a tongue depressor placed on its edge between the upper and lower incisors provides this slack). The finger inside the mouth can feel the muscle structure much more clearly than

can the finger on the outside, because the parotid gland lies between the skin and much of the midfiber portion of the muscle where many masseter TrPs are located.

Figure 8-4. Pincer palpation method for locating TrPs in the masseter muscle. A, The clinician utilizes intraoral cross-fiber pincer palpation to detect TrPs in the masseter muscle. B, Extraoral cross-fiber flat palpation technique. Both techniques can be performed with the patient seated or in a supine position.

To assess the muscle near the angle of the mandible, a cross-fiber flat palpation is utilized extraorally (Figure 8-4B). The clinician can confirm accurate palpation of the muscle by asking the patient to bite down briefly and the clinician feels a contraction under the palpating finger.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the masseter muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned masseter muscle, overuse, or maximal or submaximal concentric loading.⁷¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time.

Specifically, TrPs may be activated and perpetuated by sustained or repetitive parafunctional jaw habits such as clenching or bruxing the teeth, gum chewing, nail biting, prolonged holding of the jaw on the mouthpiece of a pipe or cigarette holder,⁷² late childhood thumb sucking, or significant occlusal disharmony loss of posterior teeth, worn denture teeth, or resorption of alveolar bone. A positive association has been demonstrated between excessive parafunctional habits and malocclusions, with nail biting found to be most common at 65.5%.⁷³ Malocclusions have been found to cause a variability of muscle activities of the masseter and temporalis muscles.⁷⁴

Other events that might activate TrPs in the masseter muscle include prolonged overstretching during a dental procedure, immobilization of the mandible in the closed position (by the head halter during continuous neck traction, or by wiring the jaw shut), direct trauma to the muscle, particularly with a blow to the side of the face, and overload of the

masseter muscle following a motor vehicle accident causing a flexion–extension injury to the suprahyoid or infrahyoid muscles, which in turn produce tension on the jaw and thereby on the masseter muscle.⁷⁵ Acute overload situations can also activate TrPs in the masseter muscle, including a sudden forcible contraction of the masseter muscle (as in cracking nuts or ice between the teeth), and biting off thread when sewing.

An excessive forward head posture can activate or perpetuate TrPs in the masseter muscle by way of increased stress to the hyoid muscles as described earlier. Chronic mouth breathing (through a surgical mask, with a continuous positive airway pressure (CPAP) machine, or due to nasal obstruction) tends to cause excessive forward head positioning and postural changes, which indirectly add stress to the masticatory muscles and may activate and perpetuate TrPs in these muscles.⁷⁶

Finally, emotional stressors can play a role in the development of TrPs in the masseter muscle. Schwartz et al⁷⁷ and Auerbach et al⁷⁸ observed the contribution of emotional stress to the development of active TrPs and pain in patients with TMD. The masseter muscles are among the first to contract in persons who are in a state of extreme emotional tension, intense determination, or desperation, and they often remain contracted for abnormally long periods of time.⁴⁶ Bell⁷⁹ presented case reports that indicate the contribution of life stress situations and bruxism to the development and perpetuation of TrP pain. People who engage in nocturnal bruxism have higher levels of salivary cortisol and perceived psychological stress,⁸⁰ which supports the idea that stress can contribute to the development of TrPs via excessive activation of the masseter muscle with bruxing.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas of other TrPs.⁸¹ Therefore, muscles in the referred pain areas for each muscle should also be considered. Facial muscles such as the corrugator supercilii and the buccinator muscles may have TrPs due to the involvement of the masseter muscle.

It is important to recognize that masseter TrPs are often associated TrPs from the sternocleidomastoid or upper trapezius muscles as a result of increased motor unit activity.^{82,83} In this situation, treatment of the TrPs in those muscles often obviates treating the masseter TrPs directly. Masseter and other masticatory muscle TrPs often resolve sufficiently with appropriate treatment of the cervical muscles, making TrP release techniques for the masticatory muscles unnecessary.

Masseter TrPs are likely to be associated with TrPs in other masticatory muscles as well. The most frequent being the ipsilateral temporalis and the contralateral masseter muscles. Less commonly, either or both the medial and lateral pterygoid muscles might be involved, and sometimes bilaterally.

4.3. Associated Pathology

Concurrent diagnoses with masseter TrPs may include TMJ internal derangements with or without reduction (refer to Chapter 18). In addition, medical conditions such as dental

disease, TTH, cervicogenic headache, tinnitus of neurologic origin, tetanus, masseter hypertrophy, and intramuscular hemangioma give rise to symptoms that can appear confusingly similar to those produced by masseter TrPs or may be present concurrently.

A diseased tooth, such as one with a nonrestorable carious lesion, can produce referred pain over the masseter muscle that closely emulates the referred pain from a TrP in that part of the muscle. Prolonged pain responses to a thermal stimulus on a tooth may indicate a pulpitis, whereas sensitivity to percussion and pressure can result from apical inflammation of the periodontal ligament.^{84, 85} Referred pain and tenderness from TrPs in the masseter (or temporalis) muscle may cause tooth hypersensitivity to any or all stimuli: occlusal pressure, percussion, heat, and cold. Appropriate treatments for pulpitis, inflammation of the periodontal ligament, and masseter TrPs are quite different, therefore making an accurate diagnosis essential.

Masseter TrPs are frequently associated with headaches. In patients with cervicogenic headache, TrPs can be a pain producing mechanism.⁸⁶ Similarly, masseter TrPs are associated with patients diagnosed with TTH.^{37, 38, 41}

Tinnitus of neurologic origin should be distinguished from that of myofascial origin as presented earlier in this chapter. Interestingly, tinnitus associated with hearing loss was frequently responsive to B₁₂ therapy,⁸⁷ if the patient was low in this vitamin. Similarly, B₁₂ therapy would help tinnitus of myofascial origin. One vitamin-inadequacy cause of tinnitus may be relieved by supplements of both niacin amide and thiamine. Restoration of normal plasma melatonin and vitamin B₁₂ blood serum levels proved helpful in patients with tinnitus associated with hearing loss.^{87, 88}

Trismus is a firm closing of the jaw caused by spasms of the masticatory muscles. It can be due to spasms of the masseter muscle from cellulitis in adjacent tissues,⁸⁹ spasms of the medial pterygoid muscle from cellulitis in the pterygomandibular space,⁸⁹ spasms of the temporalis muscle from cellulitis in the infratemporal fossa,⁸⁹ infection of the masticatory space of an odontogenic origin,^{90, 91} local anesthetic injections,^{90, 91} surgical removal of teeth⁹¹ (especially the third molar),⁹⁰ jaw or facial fractures,^{90, 91} or postradiation therapy to the facial area (radiation fibrosis).⁹¹

Although tetanus is uncommon in developed countries due to vaccinations, it is a serious medical condition that can also cause trismus and should be ruled out. As recently as 2012, in a case study by Fusetti et al,⁹² a 78-year-old farmer was diagnosed with tetanus with progressive onset of lockjaw and muscular stiffness. In addition, a 31-year-old in another case study, who had proper levels of tetanus antibodies, was treated for tetanus symptoms after puncturing his hand with a rusty nail.⁹³

Attempts to open the jaw are commonly painful with trismus. The pain is aggravated if the spastic muscles also have TrPs. Trigger points can be treated by injection, but only if there is no evidence of infection in the area. Mouth-opening exercises,⁹⁴ as well as the use of devices and medications, can help increase motion, decrease pain, and improve quality of life.^{90, 95}

Masseter hypertrophy can mistakenly be confused with pathology of the masseter

muscle because limitation of motion is a clinical finding of both conditions.^{96,97} Masseter hypertrophy is a painless swelling of the muscle at the parotid and posterior cheek area. With palpation, the masseter muscle is firm and solid with normal skin and mucosa. Magnetic resonance imaging (MRI) is positive for an increased size of muscle bundles in the masseter muscle.⁹⁸ The patient might present with limited mouth opening and occasional pain, but no fever or abnormal lab tests.^{96,97}

An intramuscular hemangioma is a rare vascular tumor that, when present in the head region, is most commonly found in the masseter muscle.^{99–101} It can be accelerated with a growth spurt or trauma to the muscular tissue and can spontaneously regress.⁹⁹ Pain is present in 50% to 60% of cases,¹⁰⁰ with a majority of the cases occurring before 30 years of age.^{99–101} Diagnostic tests such as magnetic resonance imaging, ultrasonography, and color Doppler are commonly used to help determine what type of soft-tissue lesion is present.^{99,101} Treatment is a surgical excision.^{99–101}

Pathology of the masseter muscle, as mentioned earlier, is commonly associated with TMD. Refer to other texts for comprehensive information regarding examination and differential diagnosis for TMD.

5. CORRECTIVE ACTIONS

First, because TrPs in the masseter muscle can be due to pathology in other muscles such as the sternocleidomastoid and trapezius muscles, these muscles should be addressed first (refer to Chapters 6 and 7).

Forward head posture should be corrected to reduce the masseter muscle activity. This correction might require changes to ensure that the patient can breathe through the nose, rather than the mouth. In addition, the patient should develop awareness of the mandibular posture (sternal/malar position), and reduce clenching, nail biting, exhaustive chewing, or other parafunctional oral habits.^{21,58,76} Correct tongue position, with the tongue against the roof of the mouth behind the upper incisor teeth (the “N” part of verbalizing the word “no”) can be helpful to reduce stress to the masseter muscle and minimize mouth breathing. The correct position of the tongue should be utilized during waking hours and while trying to fall asleep at night.

Stress and anxiety that lead to jaw clenching and bruxism should be managed by reducing emotional strain and by improving the patient’s ability to cope effectively. Studies have suggested that those with higher depression scores, somatic complaints, and decreased physical well-being are at a higher risk of having symptoms.¹⁰² A referral to a psychologist or other mental health provider for specific pain and stress management techniques can be very helpful due to the multiple contributory factors associated with TrPs in masticatory muscles.⁸⁹

An occlusal appliance might help minimize nocturnal bruxism and therefore potentially reduce masseter muscle activity,^{103–105} although effectiveness of these devices alone is not universally accepted.^{106,107} Combining cognitive behavioral therapy with the use of an occlusal splint results in improved outcomes,¹⁰⁸ and behavioral changes in conjunction

with occlusal devices effectively reduce masticatory myofascial pain.¹⁰⁹

The patient should also stop chewing gum, ice, or tough meat; eating caramels; biting pens, pencils, apples, or finger nails; cracking nuts with the teeth; or engaging in any other parafunctional oral behaviors that could increase the strain of the masseter muscle.

To improve mobility of the masseter muscle, the patient can perform an intraoral release (Figure 8-5) or an extraoral active release of the muscle (Figure 8-6).

Figure 8-5. Self-intraoral release of the masseter muscle. The patient places the thumb on the inside of the cheek under the masseter muscle belly and the index finger is on the outside of the cheek (over the masseter muscle). A, The digits then apply a slight compression to the muscle. B, Or the thumb may push the masseter muscle further outward to stretch the muscle.

Figure 8-6. Extraoral active release of the masseter muscle. A, The patient identifies a TrP in the masseter muscle and applies pressure to tolerance for 30 seconds with a finger. This technique is repeated 3 to 5 times, and may be performed throughout the day as needed. B, Or, while maintaining pressure on the TrP, the patient very gently closes the jaw for 3 seconds then completely relaxes and opens the jaw to gently stretch the muscle. This

technique may be repeated up to 3 to 5 times to reduce the pain and tenderness.

For patients who clench their jaw during the day, performing repetitions of jaw opening against resistance (Figure 8-7) contributes to reciprocal inhibition of the masseter muscle, thereby reducing excessive activation of the muscle.

Figure 8-7. Resisted jaw opening. With the patient's fist under their chin, the patient opens the jaw approximately 1 in against the resistance of the fist. The resisted opening should be held for 5 seconds and repeated several times throughout the day when clenching is noted.

Temporalis Muscle

“TMJ Train Wreck”

César Fernández de las Peñas and Ricardo Ortega-Santiago

1. INTRODUCTION

The temporalis muscle is one of the main muscles of the masticatory system consisting of three portions: anterior, middle, and posterior. It originates from the entire temporal fossa up to the inferior temporal line, excluding the part formed by the zygomatic bone and from the deep surface of the temporal fascia. It inserts onto the medial surface, apex, and anterior and posterior borders of the coronoid process of the mandible. It is innervated by the anterior and posterior deep temporal nerves, which branch from the anterior division of the mandibular portion of the trigeminal nerve (cranial nerve V). The vascularization of the temporalis muscle is supplied by the deep temporal branches from the second part of the maxillary artery. It is one of the main contributors to the dynamic stability of the temporomandibular joint by controlling the movement during mouth closing. Its primary function is closing the mouth, although the posterior fibers can assist in lateral movement to the same side, whereas the anterior fibers can contribute to the protrusion of the jaw. The referred pain from the temporalis muscle produces tooth pain or deep head pain, depending on the clinical presentation of the patient. This muscle is commonly involved in different pain syndromes of the craniocervical system, particularly in headaches, temporomandibular pain disorders, orofacial pain, and mechanical neck pain. In the last decade, there has been increasing evidence of the contribution of active trigger points (TrPs) in the temporalis muscle in symptoms associated with tension-type headache (TTH) and temporomandibular pain disorders (TMDs). Symptoms can spontaneously occur, and they may often be perpetuated by dysfunctional habits such as bruxism, chewing gum, biting fingernails, and chewing ice. It has been demonstrated that the temporalis muscle exhibits pressure pain hypersensitivity, expressed as lower pressure pain thresholds, in people with headache. Corrective actions include maintaining good postural alignment, proper tongue resting position in the mouth, stopping parafunctional habits, and passively stretching the muscle.

2. ANATOMIC CONSIDERATIONS

The temporalis muscle originates from the entire temporal fossa up to the inferior temporal line, excluding the part formed by the zygomatic bone, and from the deep surface of the temporal fascia. It inserts onto the medial surface, apex, and anterior and posterior borders of the coronoid process of the mandible (Figure 9-1).¹ A thick temporalis fascia, which splits into superficial and deep layers approximately 2 cm superior to the zygomatic arch, covers this muscle. Between the superficial and deep fascia lies the superficial temporal fat pad.

Figure 9-1. Attachments of the temporalis muscle, inferiorly, are chiefly to the coronoid process of the mandible and, superiorly, to the temporal fossa. The anterior fibers of this fan-shaped muscle are nearly vertical, and the posterior fibers are nearly horizontal but change direction and exert a mostly upward pull. The zygomatic arch, which has been partly removed, covers much of the tendinous attachment of the muscle to the coronoid

process unless the mouth is opened.

The temporalis muscle can be divided into three portions, depending on the orientation of the fibers: the anterior fibers that are nearly vertical, the middle fibers that are oblique, and the posterior fibers that are nearly horizontal.¹ With the different fiber directions, there is also a difference in the composition of fiber types of the muscle, which is due to specific portions of the muscle being more active than others portions of the muscle for a given task, that is, chewing. It is known that the muscle is comprised of both Type-I (slow twitch) and Type-II (fast twitch) fibers^{2,3}; however, studies have shown discrepancies as to the percentage of Type-I fibers in different parts of the muscle.^{2,4}

2.1. Innervation and Vascularization

The innervation of the temporalis muscle is supplied by the anterior and posterior deep temporal nerves, which branch from the anterior division of the mandibular portion of the trigeminal nerve (cranial nerve V). In addition, the vascularization of the temporalis muscle is supplied by the deep temporal branches from the second part of the maxillary artery.¹ In addition, the temporal arterial system provides reliable vascular anatomy for the temporalis muscle flap.⁵

2.2. Function

All the fibers of the temporalis muscle contribute to its primary function of elevation of the mandible (mouth closing). This movement requires both the upward pull of the anterior fibers and the backward pull of the posterior fibers.¹ When the mandible is closed and the jaw is clenched tightly in centric occlusion, the temporalis muscle is activated before the masseter muscle and all parts of the temporalis muscle are involved.^{6,7} Interestingly, the temporalis muscle has demonstrated an antagonistic contraction during mouth opening in patients with masseter muscle contracture.^{8,9}

The temporalis muscle also contributes to side-to-side movements of the mandible. Lateral movements of the mandible to the same side consistently activate the temporalis muscle, with the posterior fibers activated more than its anterior fibers.^{10,11} Cecílio et al⁷ reported similar findings; however, the portion of the temporalis muscle was not specified in their study.

Finally, this muscle is also involved in retrusion and protrusion of the mandible. For retrusion, all fibers of the temporalis muscle are active; however, the posterior fibers have demonstrated higher electromyographic (EMG) peak activity than the anterior fibers with this motion.¹¹ This supports earlier studies that reported similar findings.¹²⁻¹⁴ Research in this area has not been done of late. For protrusion, the muscle is active, although not as strongly as during retrusion⁷ and it is thought that the anterior fibers are more active with this motion.¹⁰

In the mandibular rest position, the anterior fibers of the temporalis muscle are

active.¹⁵ Other studies, however, have conflicting opinions—one study reported that the posterior fibers are more active than the anterior fibers,¹⁶ whereas another found no activity in repeated recordings of three temporalis muscles in seated subjects at rest with the head and trunk erect.¹⁷ These differing conclusions could result from the variation in the rest position, differences in the degree of anxiety-induced muscle tension, variations in electrode technique, head position, and the presence of latent TrPs in the masticatory musculature.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 9-1 grossly represents the functional unit of the temporalis muscle.¹⁸

Box 9-1 Functional unit of the temporalis muscle

Action	Synergists	Antagonist
Mandibular elevation	Masseter Medial pterygoid	Lateral pterygoid (inferior division) Digastric Omohyoid Mylohyoid

In addition to its primary function of mandibular elevation, the temporalis muscle can assist with ipsilateral mandibular elevation. The role of the superior division of the lateral pterygoid muscle during mandibular elevation (mouth closing) is under debate, although it is claimed that this muscle acts in eccentric contraction to recapture the disc during the movement.¹⁹

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The temporalis muscle is commonly involved in patients with TTH^{20–22} or TMD.²³ Interestingly, the temporalis muscle is also highly involved in children with TTH.²⁴ The referred pain elicited by TrPs in the temporalis muscle is described as pain felt widely throughout the temple, along the eyebrow, retro-orbitally, and in any or all the upper

teeth.²⁵ Temporalis TrPs might also cause hypersensitivity to percussion and to moderate temperature changes that appears in any or all the upper teeth on the same side, depending on the TrP location.²⁵ Trigger points can be located in any portion of the temporalis muscle. It has been clinically observed that the anterior portion of the temporalis muscle can refer pain forward along the supraorbital ridge and downward to the upper incisor teeth²⁵ (Figure 9-2A). Trigger points in the middle portion of the muscle can refer pain upward in finger-like projections to the midtemple area and downward to the intermediate maxillary teeth on the same side (Figure 9-2B and C). Finally, TrPs located in the posterior portion of the muscle can refer pain backward and upward inside to the head, mimicking headache features (Figure 9-2D).²⁵ Other studies have also examined the referred pain patterns of the temporalis muscle with injections of hypertonic saline. Jensen and Norup²⁶ found that the muscle referred to the jaw. Schmidt-Hansen et al²⁷ reported referred pain to trigeminal innervated dermatomes, particularly to the ophthalmic and mandibular areas. The differences in the reported pain patterns highlight clinicians should consider that any portion of the temporalis muscle can refer pain to any part of the head or the teeth.

Figure 9-2. Patterns of pain and tenderness referred from trigger points (TrPs) in the left temporalis muscle (essential zone solid red, spillover zone stippled). A, referred pain from TrPs in the anterior portion of the temporalis muscle; B and C, represent referred pain arising from TrPs in the middle portion of the temporalis muscle; D, referred pain from TrPs in the posterior portion of the muscle.

More recent studies have tried to represent the anatomic location of the referred pain from TrPs located in the temporalis muscle in individuals with TMD or TTH. Alonso-Blanco et al²⁸ observed that women with TMD exhibited more active TrPs in the

temporalis and masseter muscles than women with fibromyalgia syndrome. In addition, the referred pain was located more posteriorly in TMD women. In another study, the same authors found that children with TTH had larger referred pain areas than adults for the temporalis muscle, but the referred pain area of temporalis muscle was located more inferiorly in adults with TTH than in children with TTH.²⁹ Finally, a clinical study investigating topographical distribution of TrPs in the temporalis muscle in patients with TTH observed two important findings for clinical practice: (1) the temporalis muscle usually exhibits multiple active TrPs in the same patient; (2) TrPs are mainly located in the anterior and the middle portions of the muscle belly.³⁰

3.2. Symptoms

Patients with temporalis TrPs might report having a headache, either TTH or migraine, toothache or tooth site pain, as previously described, but they are rarely aware of any restriction of jaw opening, which is usually reduced only by 5 to 10 mm (about 3/8 in). It is the masseter muscle that more frequently induces limitation of jaw opening (refer to Chapter 8). Thus, ordinary mandibular movement does not usually cause pain with TrPs in the temporalis muscle. It seems that a common phenotypic hyperalgesic response in the temporalis muscle in people with headache is expressed as lower pressure pain thresholds.³¹ It is interesting to note that in clinical practice, the referred pain elicited by TrPs in the temporalis muscle adopts the phenotypic symptoms of the patient, that is, in a patient with TMD, the temporalis muscle refers pain to the teeth or the mouth, but not to the head, whereas in a patient with TTH, the referred pain is perceived deep into the head, but not into the teeth. Patients with TMD might say, “My teeth don’t meet right,” whereas patients with TTH or migraine might say, “I feel my pain inside the head or into the eye like an eye mask.” Because of the potential for attendant hypersensitivity in teeth in the referred site of pain, unaware dental providers may needlessly extirpate pulps or extract perfectly healthy teeth.²⁵

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The clinician should perform a screening examination of the temporomandibular joint and should assess the patient’s posture, with particular attention to head and neck positions. Forward head posture and excessive tension in suprahyoid and infrahyoid muscles should be noted, although the relation between TMD and head and neck postures is still controversial and unclear.³²

The patient performs active mouth opening and closing. Normal or functional mouth opening can be determined by attempting to place a tier of the proximal interphalangeal joints of the first two fingers of the non-dominant hand between the upper and lower incisor teeth (two-knuckle test). Usually, about 2½ knuckles of mouth opening can be

reached if the temporalis muscle, but not the masseter muscle, is involved. When the posterior fibers of the temporalis muscle have TrPs, the mandible is likely to show a C-curve during mouth opening and closing.

3.4. Trigger Point Examination

Palpation of the temporalis muscle often reveals very painful TrPs even when it is conducted smoothly. Trigger points can be found in any portion of the muscle belly, although the anterior portion is the most commonly affected.³⁰ Each of the three portions should be examined carefully. Knowledge of fiber direction is critical as cross-fiber flat palpation should be performed perpendicular to the muscle fibers to locate the taut band and then identify TrPs within the taut band. Local twitch responses are moderately difficult to elicit by snapping palpation.

The temporalis muscle can be examined with the patient sitting or preferably supine. The jaw should be partially open to place the muscle fibers on the degree of stretch required to optimize the palpation of the temporalis TrPs. When the jaw is closed and the muscle is fully shortened, its palpable bands are can be more difficult to feel; they are less tender, and the local twitch response to cross-fiber palpation may be unobtainable. When the patient allows the jaw to drop in the relaxed open position while keeping the lips gently closed or just slightly apart, it takes up the slack for examination of this muscle (Figure 9-3). Cross-fiber flat palpation of the temporalis muscle usually discloses multiple taut bands in the muscle. Because this muscle usually exhibits multiple TrPs, the presence of one tends to activate others, and pressure on either can frequently produce similar referred pain patterns.

Figure 9-3. Examination of the TrPs in the anterior portion of the temporalis muscle. For examination of all portions, the patient should allow the lower jaw to drop into the relaxed open position (lips remaining gently closed) to take up slack in the muscle. This accentuates firm bands of muscle fibers, increases the spot tenderness and referred pain of a TrP to pressure, and increases the sensitivity of the TrP response to snapping palpation to test for a local twitch of the taut band fibers.

In some patients with TMD pain, TrPs can be located in the part of the muscle close to the coronoid process. The examination of the temporalis muscle for this TrP is conducted with the patient's mouth opened, and the TrP is palpated internally on the inner surface of the coronoid process, with pressure directed outward against the coronoid process. The temporalis muscle is not known to cause nerve entrapment.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the temporalis muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. For example, excessive gum chewing or parafunctional habits such as bruxism or jaw clenching can not

only initiate but perpetuate TrPs in the temporalis muscle. Additionally, patients who use an over the door cervical traction device for neck pain without a dental splint cause immobilization of the mandible in the fully closed position, causing maximum shortening of the temporalis and other mandibular elevator muscles. A traction unit in the supine position should be used instead to minimize undue strain to the jaw. For patients who visit the dentist, TrPs in the temporalis muscle can develop when the mouth has been kept in an open position for a prolonged period of time. This situation can be considered as an iatrogenic activation of temporalis muscle TrPs. Iatrogenic temporalis TrPs might then add the symptoms of facial pain, toothache, and possibly altered occlusion to the initial complaint.

Sudden trauma such as whiplash in an auto accident,^{34,35} or direct trauma to the muscle, as from a fall on the head, blow to the face, impact from a golf ball or baseball, or impact of the head against the side of the car in a motor vehicle accident can also cause TrP formation.

An anteriorly displaced disc of the TMJ might cause the patient to experience a feeling of pressure. In an attempt to do something to relieve the sense of pressure, the patient might bite down, which does not correct the disc problem and only perpetuates temporalis (and masseter) TrPs.

Often overlooked or forgotten is the reflex muscle contraction occurring with chronic infection or inflammation. When prolonged, this is believed to contribute to the development of TrPs. Thus, true painful pulpal pathology or an inflamed TMJ, if protracted, may cause temporalis (or other masticatory muscle) TrPs to develop. These TrPs become self-sustaining, and even after resolution of the pulpal pathology or inflamed joint, may continue to cause intermittent or constant pain, typically referred back to the original site of pain. The unaware clinician, unfortunately, continues to treat the tooth or the joint instead of the TrPs, with potentially negative results.

The mandibular position induced by a forward head posture can produce increased activity in the temporalis muscle and can activate and/or perpetuate TrPs. Excessive tension in the suprahyoid and infrahyoid muscles can create light tensile forces, which pull down on the mandible and require the temporalis and masseter muscles to contract to counteract the pull and keep the mouth closed, resulting in the activation or perpetuation of TrPs in these muscles.³⁶

Especially when the patient is fatigued, temporalis TrPs may be activated by a cold draft over the muscle (eg, a blast of cold air from an air conditioner or wind through an open car window).²⁵ Persons with low-normal serum levels of thyroid hormones (T3 and T4 by radioimmunoassay), as well as people with hypothyroidism, are particularly vulnerable to such muscle cooling.

Temporalis TrPs might be activated by associated TrPs when they lie within the pain reference zone of TrPs in the upper trapezius and sternocleidomastoid muscles. Trigger points in leg muscles have also been observed to indirectly cause a reduction of maximal interincisal opening, and thus may influence masticatory muscle function.^{37,38} This phenomenon is an example of dysfunction set up by dynamic and static postural

asymmetries, in this instance originating in a weight-bearing limb.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs (Hsieh et al., 2007). Therefore, musculature in the referred pain areas for the temporalis muscle should also be considered. Muscles in the referred pain areas of the temporalis muscle include the corrugator and masseter. Temporalis TrPs are also likely to be associated with TrPs in the other masticatory muscles. The most frequent being the ipsilateral masseter and the contralateral temporalis muscles. Less commonly, either or both the medial and lateral pterygoid muscles might be involved, sometimes bilaterally.

Associated TrPs often develop in the temporalis muscle from TrPs in the commonly involved upper trapezius³⁹ and sternocleidomastoid muscles. In fact, TrPs in the masticatory muscles are also highly prevalent in individuals with mechanical neck pain.⁴⁰

4.3. Associated Pathology

Some medical conditions give rise to symptoms that can appear confusingly similar to those produced by temporalis TrPs or may be present concurrently. Concurrent diagnosis may include TMJ internal derangements. Other medical conditions include dental disease, TTH, cervicogenic headache, migraine, polymyalgia rheumatica, temporal arteritis, and temporal tendinitis. One of the main medical diagnoses that should be excluded before treating temporalis TrPs is temporal arteritis.

A diseased tooth, such as one with a non-restorable carious lesion, can produce referred pain over the temporalis muscle that closely emulates the referred pain from a TrP in that part of the muscle.

The head pain of polymyalgia rheumatica is distinguished from that due to temporalis TrPs in several ways. First, by the more extensive distribution of the *bilateral* pain of polymyalgia that usually includes the shoulders, and often the neck, back, upper arms, and thighs. Second, the erythrocyte sedimentation rate is increased. Third, morning stiffness commonly lasts more than 45 minutes, and finally, the age of the patient is more than 50 years.^{41, 42}

The diagnosis of temporal tendinitis can be based on tendon-attachment enthesopathy that results from TrPs in the temporalis muscle. The clinician should examine for that possibility before proceeding with palliative care or steroid injections, or worse, a more drastic surgical procedure such as excising the condylar attachment of the muscle.⁴³ If temporalis TrPs are responsible for the symptoms, inactivating them is much simpler, less invasive, less painful, and less expensive.

An important differential diagnosis is giant cell arteritis or temporal arteritis, a systemic inflammatory vasculitis of unknown etiology occurring in older persons and can result in a wide variety of medical complications. Common signs and symptoms of temporal arteritis include visual disturbances, headache, jaw claudication, neck pain, and scalp tenderness. Therefore, some of these symptoms can overlap those originated in temporalis muscle TrPs.

This is important because a recent study has observed that the temporalis muscle is also affected in around 20% of patients with temporal arteritis.⁴⁴

5. CORRECTIVE ACTIONS

The patient should be instructed to maintain good head and neck postures and effective resting jaw and tongue position to correct the problems of forward head posture and aberrant tongue position. Instructions on body mechanics and ergonomics are also essential. In addition, most patients need to learn general neck stretching exercises to help inactivate any TrPs in the cervical muscles that may be perpetuating the temporalis TrPs. In fact, in some patients, TrPs resolve following correction of these two powerful perpetuating factors alone.

Body asymmetry and the resultant functional scoliosis should be corrected by appropriate lifts, because this postural stress may activate TrPs in the neck muscles that cause associated TrPs in the masticatory muscles. If the habit of mouth breathing produces forward head posture, mouth breathing should be corrected by eliminating contributory factors such as nasal obstruction.

When the temporalis muscle has shortened in association with an occlusal abnormality, the muscle should be stretched to its normal resting length prior to being fitted for dental appliances, so that they can be adjusted to work properly. Correct neutral head position is also critical during adjustment of any appliances. If the head is in extension in the dental chair, the occlusion will be different from that when the patient is sitting or standing with correct head and neck alignment. Goldstein et al⁴⁵ found that a forward head posture alters the forces of the path of mandibular closure by increasing the activity of the masticatory muscles in maximal intercuspal position at rest.

The activation of TrPs during a prolonged dental procedure may be prevented by taking breaks for the patient to go through several cycles of active range of motion.

Prolonged maximal shortening of the muscle during sleep may be prevented by a “night guard” or occlusal splint with a flat occlusal plane, which keeps the upper and lower teeth a few millimeters apart and can relieve bruxism.^{46–48} This is especially helpful during periods of high stress.⁴⁹ For more significant benefit, cognitive behavioral therapy can be undergone in addition to the use of an occlusal splint because this has been shown to be more effective than splint use alone.⁵⁰

The patient should be persuaded to stop chewing gum, ice, or tough meat; eating caramels; biting pens, pencils, apples, or their finger nails; cracking nuts with the teeth; or engaging in any other parafunctional behaviors of the teeth or mouth. The patient should avoid cold drafts that blow directly on the temple by wearing a nightcap, protective hood, or scarf.

The patient should learn how to passively stretch the temporalis in the seated position by doing the temporalis self-stretch exercise daily (Figure 9-4). Caution should be exercised not to overstretch this muscle, because this will place abnormal forces on joint structures. Before this exercise is done, the patient might apply moist heat over the temporalis muscle,

covering the side of the head and face for 10 to 15 minutes before retiring at night.

Figure 9-4. Self-stretch of the temporalis muscle. The jaw elevator muscles are elongated by pulling down firmly with broad pressure of the hands on the side of the head and face, stretching the temporalis muscle while taking in a long full breath to augment muscle relaxation.

When the patient is comfortable with the passive exercise described above, the next step is initiating an active-resistive mouth-opening exercise, which helps overcome restricted motion through reciprocal inhibition. The patient can release the muscle by lightly resisting opening of the mouth (with two fingers below the chin) for a few seconds, followed by active opening of the mouth to take up slack in the muscle. The amount of opening can be controlled with correct tongue position on the hard palate behind the upper teeth. This protective maneuver is recommended for patients with TMJ inflammation or painful TMJ

derangements (ie, disc displacement with reduction), so that they will stretch within the nonpainful limits or avoid the painful click.

If the posterior fibers of the temporalis muscle are involved, causing the mandible to deviate on opening, the patient should modify the above exercise: the patient opens the jaw to stretch while first placing one hand against the opposite maxilla (contralateral to the involved temporalis) and the other hand against the ipsilateral side of the mandible. The lower jaw is pushed away from the side toward which it deviates during opening, while the patient actively assists the motion with the jaw muscles for the most effective stretch. The mandible is gently restored to the starting position before the pressure is fully released. Placing the tongue in its resting position during this exercise also promotes symmetrical mouth opening. When full relief is obtained, the exercises might be reduced to 2 or 3 times weekly as a health maintenance measure and be incorporated into a regular postexercise muscle stretching routine.

If there is no articular dysfunction, the patient is encouraged to induce a wide-open yawn as a regular exercise. The addition of this reflex inhibition helps obtain full normal stretch length of the temporalis muscle (and other mandibular elevator muscles).

Finally, the patient should be checked for evidence of reduced thyroid function, other metabolic disorders, and nutritional deficiencies, any of which might increase neuromuscular irritability, as described in Chapter 4.

Medial Pterygoid Muscle

“Deep Deceiver”

Michelle Finnegan and Joseph M. Donnelly

1. INTRODUCTION

The medial pterygoid muscle is an important muscle of mastication that lies deep to the mandible. It is comprised of two heads, the superficial and deep, that work together closely to support the jaw along with the masseter and lateral pterygoid muscles. The deep head originates from the inner surface of the lateral pterygoid plate of the sphenoid bone, just deep to the lateral pterygoid muscle. The superficial head attaches to the maxillary tuberosity just above the third molar and to the pyramidal process of the palatine bone. Both heads insert to the medial surface of the lower border of the ramus and angle of the mandible. The muscle is innervated by the medial pterygoid branch of the mandibular division of the trigeminal nerve. It receives vascularization from the pterygoid branches of the maxillary artery. The muscle functions bilaterally to close the mandible, whereas unilaterally it deviates the jaw to the contralateral side. Trigger points (TrPs) in this muscle can refer to the temporomandibular joint (TMJ), ear, and parts of the mouth. They can also contribute to many different otolaryngic symptoms and pain in the teeth, making differential diagnosis essential for proper treatment. Medial pterygoid TrPs can be perpetuated by parafunctional habits, forced contraction of the muscle like when biting down hard on food, mouth breathing, and stress. Although not researched as extensively as other muscles influencing the TMJ, this muscle can be involved in temporomandibular dysfunction (TMD). Pathologies associated with this muscle include entrapment of the lingual nerve, facial asymmetry due to muscle hypertrophy, trismus, myositis ossificans, and oromandibular dystonia. Corrective actions include addressing posture and tongue positioning, eliminating parafunctional habits, eliminating TrPs in cervical muscles that can refer to the region of the medial pterygoid, stress management, and resisted jaw opening exercises.

2. ANATOMIC CONSIDERATIONS

The medial pterygoid muscle is a thick quadrilateral muscle that consists of two heads (deep and superficial) (Figure 10-1A and B). The larger, deep head of the medial pterygoid muscle commonly originates from above to the medial (inner) surface of the lateral pterygoid plate of the sphenoid bone, just deep to the inferior head of the lateral pterygoid muscle^{1,2}; however, variations with attachments to the pterygoid fossa have been reported.³

The smaller superficial head of the medial pterygoid muscle attaches to the maxillary tuberosity just above the third molar⁴ and to the pyramidal process of the palatine bone by a strong tendinous cone,³ passing over the lateral surface of the lateral pterygoid plate, and covering the lower end of the inferior head of the lateral pterygoid muscle.¹ Sakamoto and Akita² reported that this portion of the muscle is only attached to the lateral surface of the pyramidal process of the palatine bone.

Both heads of the medial pterygoid muscle descend posterolaterally almost in parallel with the masseter muscle, inserting by a short aponeurosis to the medial surface of the lower border of the ramus and the angle of the mandible (Figure 10-1B).^{1,3} Variations in its insertion can be as far posterior as the mandibular fossa and as far anterior as the mylohyoid groove of the mandible.¹ Variations in these attachments are likely due to the insertions' composition of alternating tendinous sheets and fleshy fibers that partly cover themselves as they attach to the ramus and angle of the mandible. Seven layers of this muscle have been reported, all with slightly different insertions.³

An accessory bundle of the medial pterygoid muscle may be present, inserting just superior to the mylohyoid line. It can also be identified as a part of the posterior region of the mylohyoid muscle.²

Along with the medial pterygoid muscle, the inferior division of the lateral pterygoid muscle (Figure 10-1A, light red) on the inside of the mandible and the masseter muscle on the outside suspend the angle of the mandible like a sling.

The anterior and lateral parts of the medial pterygoid muscle has a high percentage of Type-I (slow twitch) fibers (reported as high as 79%) whereas the posterior and medial portions have, as in most skeletal muscles, approximately half Type-I fibers (52%).^{5,6} Also, the medial pterygoid muscle has a high percentage of hybrid fibers, as well as a small percentage of Type-IIA and -IIX fibers^{2,6-8} compared with muscles that open the jaw. Differences in the studies of fiber type are likely due to the way the fiber types were assessed.

2.1. Innervation and Vascularization

Typically, the medial pterygoid muscle is supplied by the medial pterygoid branch of the mandibular division of the trigeminal nerve (cranial nerve V),^{1,2} though a small branch from the lingual nerve can innervate the posterolateral portion of the muscle.² When present, the accessory muscle bundle is innervated by a small branch of the lingual nerve.²

Vascularization of the medial pterygoid muscle is supplied via the pterygoid branches of the maxillary artery.^{1,9}

2.2. Function

Acting unilaterally, the medial pterygoid muscle deviates the mandible toward the contralateral side.^{1,9,10} This lateral motion is especially important during the grinding motions of chewing, which require fine control.

Bilaterally, the medial pterygoid muscles help elevate the mandible (close the jaw) along with the masseter and temporalis muscles.^{1,9} The activity of the medial pterygoid muscle is increased if the mandible is protruded while it is being elevated.⁹ Together, these muscles also have a minor contributory role in protrusion of the mandible.⁹⁻¹¹

Figure 10-1. Attachments of the medial pterygoid muscle (dark red) and its relation to the lateral pterygoid muscle (light red). A, Lateral view showing the medial pterygoid muscle on the inner side of the mandible. Part of the mandible and the zygomatic arch have been removed. B, Coronal section of the skull just behind the temporomandibular joint, looking forward inside the mouth. The medial pterygoid muscle attaches, above, to the medial (inner) surface of the lateral pterygoid plate of the sphenoid bone and, below, to the medial surface of the mandible near its angle.

The medial pterygoid muscle is active bilaterally with chewing; however, the activity is higher on the side that the chewing occurs on.^{12–14} Similar to the lateral pterygoid muscle, this muscle has also demonstrated heterogeneous activation,¹⁵ with the anterior and posterior portions of the muscle being active during different clenching tasks. The posterior portion demonstrates greater activity during anterior and anterolateral clenching, whereas the anterior region showed greater activity with anteromedial, medial, and posterolateral clenching.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 10-1 grossly represents the functional unit of the medial pterygoid muscle.¹⁶

Box 10-1 Functional unit of the medial pterygoid muscle

Action	Synergists	Antagonist
Contralateral mandibular deviation	Ipsilateral lateral pterygoid Contralateral masseter Contralateral temporalis	Contralateral lateral pterygoid Contralateral medial pterygoid
Mandibular elevation	Masseter Temporalis	Lateral pterygoid Digastric muscles
Mandibular protrusion	Lateral pterygoid	Temporalis Masseter

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the medial pterygoid muscle refer pain in poorly demarcated regions related to the mouth (tongue, pharynx, and hard palate), below and behind the TMJ, and deep in the ear (Figure 10-2).¹⁷⁻¹⁹ Others have found that pain can be referred to the retromandibular and infra-auricular area,^{19,20} including the region of the lateral pterygoid muscle, the floor of the nose, and the throat.²¹ Although Simons et al¹⁶ reported that the medial pterygoid muscle does not refer to the teeth, Svensson et al²² reported that the muscle refers to the maxillary and mandibular molars and gingiva, the mandibular premolars, the gingiva of the maxillary and mandibular premolars, and the gingiva of the front maxillary teeth with injections of hypertonic saline. They also reported the muscle referred along the entire length of the ipsilateral mandible, more extensively throughout the ear, as well as into the anterior neck, just below the mandible.

Figure 10-2. Referred pain pattern (red) in the left medial pterygoid muscle. A, Referral pattern to temporomandibular joint (red) and lateral neck (stippled). B, Anatomic cut-away to show the location of the TrP area in the muscle, which lies on the inner side of the mandible. C, Posterior to anterior view of a coronal section of the head through the temporomandibular joint. Internal areas of pain also appear as stippled red.

Stiffness of the ear may also be a symptom of medial pterygoid TrPs. For the tensor veli palatini muscle to dilate the Eustachian tube, it should push the adjacent medial pterygoid muscle and interposed fascia aside. In the resting state, the presence of the medial pterygoid muscle helps to keep the Eustachian tube closed. Tense TrP bands in the medial pterygoid muscle might block the opening action of the tensor veli palatini muscle on the Eustachian tube producing baro hypoacusis (ear stuffiness).¹⁶

3.2. Symptoms

Patients with TrPs in the medial pterygoid muscle report that pain increases with attempts to open the mouth wide, with chewing food, or with clenching the teeth. Jaw-opening is usually restricted as well.

Patients describe pain from the medial pterygoid muscle as being more diffuse than the pain referred from TrPs in the lateral pterygoid muscle. Svensson et al²² reported that the most common descriptors with involvement of this muscle included boring, shooting, hot, and aching. Those less commonly used were taut, spreading, tight, intense, sharp, and pressing.

Teachey²³ has reported several different symptoms of the nose, sinus, ears, throat/neck, mouth, and teeth/gums with medial pterygoid TrPs. Symptoms specific to the nose include nasal pain, congestion, “obstruction,” or pressure. Patients may be given the diagnosis of paradoxical nasal obstruction. Although the lateral pterygoid muscle is more frequently associated with sinus pain and “sinusitis,” the medial pterygoid muscle has been shown to contribute to these symptoms as well. Symptoms specific to the ear include ear pain, clogging, foreign body sensation, “blocked” ears, hyperacusis, hypoacusis, hearing loss, tinnitus, and dizziness. When otolaryngic studies are normal, including an audiometric evaluation, TrPs should be considered as a cause of these symptoms. Symptoms related to the throat/neck may include chronic/recurrent discomfort, sore throat, or tonsillitis; dysphagia; odynophagia; burning sensations; throat “congestion”; throat “drainage”; and voice irregularities. Medial pterygoid TrPs may also cause pain or burning of the mouth or pain to the teeth and/or gums.

Finally, TrPs in this muscle might be the cause of a patient’s report of stuffiness of the ears, especially if a medical examination is unremarkable.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The clinician should perform a screening examination of the TMJ and should assess the patient’s posture, with particular attention to head and neck position. Although the relationship between TMD and the head posture is somewhat controversial and unclear,²⁴ it is thought that forward head posture indirectly induces tension in the supra- and infrahyoid muscles, which in turn pulls downward to create light tensile forces on the mandible.²⁵ As a result, this tension causes the mandibular elevator muscles such as the medial pterygoid (and masseter) muscle to contract to keep the mouth closed.

Mandibular opening is usually restricted in patients with medial pterygoid TrPs. A quick functional screen to assess the opening is with the two-knuckle test (refer to Chapter 8). Patients are usually not able to pass this test when TrPs in the medial pterygoid muscle are present. If preferred, a standardized way to objectively measure mouth opening is with a disposable vertical ruler to measure the distance between the upper and lower incisors.^{26, 27}

Normal opening for women is 41 to 45 mm and 43 to 45 mm is typical for men.^{28, 29}

3.4. Trigger Point Examination

For examination of the medial pterygoid muscle, the patient should be in supine position with the jaw open as far as is comfortable to take up any slack in the muscle. A cross-fiber flat palpation for TrPs in the midmuscle region is performed with the mouth open, intraorally with gloved fingers (Figure 10-3A). The pad of the palpating index finger faces outward and slides over the molar teeth until it encounters the bony anterior edge of the ramus of the mandible, which lies behind and lateral to the last molar tooth. The belly of the medial pterygoid muscle lies immediately beyond (posterior to) this bony edge. The muscle can be identified by having the patient alternately clench and relax against a block or cork placed between the teeth while the operator palpates for the changes in tissue tension. The orientation and texture of this muscle are readily palpable because only a thin layer of mucosa separates the palpating finger from the muscle. Palpation will elicit exquisite tenderness in the patient with medial pterygoid TrPs.

Figure 10-3. Examination of the medial pterygoid muscle for TrPs. A, Intraoral palpation (with a gloved hand) of TrPs behind the last molar tooth, with the muscle and the ramus of the mandible between the palpating digits. The mouth is opened wide enough for the finger to be placed between the molar teeth. The clinician may wish to prop the mouth open with a cork to protect the finger and help the patient to relax. B, Extraoral palpation

of TrPs in the region of the attachment of the muscle to the inner surface of the mandible, at its angle.

If there is concern for the safety of the examining finger in the mouth, the block or cork can be left in place between the patient's teeth throughout the TrP examination.

Palpating this muscle through the pharyngeal mucosa may make the patient gag, therefore palpation should always be done slowly and cautiously. One way to reduce the gag reflex is to tap the ipsilateral temporalis muscle to provide sensory distraction during the examination. Another technique is to have the patient curl the tip of the tongue as far as possible down the throat behind the molar teeth on the opposite side. The harder the patient forces the tongue backward and down the throat, the less sensitive the reflex becomes.

To palpate for TrPs extraorally, the head is tilted slightly toward the side to be palpated to slacken tissues and improve access to the muscle. One finger examines the inner (medial) surface of the mandible by pressing upward at its angle (Figure 10-3B). The firm mass, approximately 1 cm (3/8 in) above the angle of the mandible, just within the reach of the finger, is the inferior part of the mandibular attachment of the muscle. Pressure is exerted inward to the muscle to assess for TrPs. The specific cross-fiber palpation cannot be performed to assess the muscle from this direction because only the attachment of the muscle is accessible. To confirm the muscle's location, the patient can actively clench their teeth together. The clinician feels the contraction under the tip of the palpating finger. Exquisite tenderness with palpation indicates TrP activity in the muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the medial pterygoid muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³⁰ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.³⁰ Specifically, excessive gum chewing or parafunctional habits such as bruxism, jaw clenching, nail biting, or persistent thumb-sucking by a child can not only initiate but perpetuate TrPs in the medial pterygoid muscle. Excessive chewing on one side contributes to overload in the ipsilateral medial pterygoid muscle.¹²

Acute overload situations can also activate TrPs in the medial pterygoid muscle, including a sudden forcible contraction of the muscle (as in cracking nuts, chewing ice, or using the teeth to tear thread).

Trigger points in the medial pterygoid muscle may be activated by excessive forward head posture that places mild but persistent stress on the medial pterygoid (along with the masseter and temporalis) muscle by way of increased stress to the hyoid muscles, as described earlier.

Chronic mouth breathing (as through a continuous positive airway pressure [CPAP] machine, or due to nasal obstruction) also tends to cause excessive forward head positioning and postural changes that indirectly add stress to the masticatory muscles and may activate and perpetuate TrPs in these muscles.³¹

The medial pterygoid muscle on one side may develop and retain TrPs because of the increased stress imposed on it by TrP activity and distorted function of the muscle on the opposite side. Activation and perpetuation of medial pterygoid TrPs can also be secondary to the muscular dysfunction that results from TrPs in the lateral pterygoid muscle.

In the past, occlusal imbalance was considered one cause for the activation of medial pterygoid TrPs. It is now thought that the abnormal muscle tension caused by TrPs in masticatory muscles, including the medial pterygoid muscle, can cause the occlusal abnormalities. Masticatory muscle myofascial TrPs should be inactivated prior to initiating any prosthodontic treatment.

Other factors that can contribute to the development of TrPs in the medial pterygoid muscle include anxiety and stress.

4.2. Associated Trigger Points

Associated TrPs can develop in muscles within the referred pain areas of other TrPs.³² Therefore, musculature in the referred pain areas for each muscle should also be considered. Muscles such as the sternocleidomastoid and masseter muscles can contribute to the development of TrPs in the medial pterygoid muscle. Trigger points of the medial pterygoid muscle can also contribute to the associated TrPs in other muscles including the masseter, lateral pterygoid, and posterior digastric muscles.

The medial pterygoid muscle usually develops TrPs in association with functionally related muscles, including the lateral pterygoid, masseter, and temporalis muscles.

If the patient continues to have difficulty in swallowing following the inactivation of the medial pterygoid TrPs, the sternocleidomastoid (see Chapter 7), the digastric, and possibly the longus capitis and longus colli muscles (see Chapter 12) should be examined.

4.3. Associated Pathology

Some medical conditions give rise to symptoms that can appear confusingly similar to those produced by medial pterygoid TrPs or may be present concurrently. Concurrent diagnosis may include TMD (refer to Chapter 18). Other medical conditions include dental disease, nerve entrapment, myositis ossificans, trismus, otolaryngic symptoms, and oromandibular dystonia.

Because this muscle refers to the TMJ, misdiagnosis of joint involvement can easily be mistaken for pain associated with TrPs of the medial pterygoid muscle; therefore, a thorough examination of all the structures related to the TMJ is essential. In patients with TMJ ankylosis, the medial pterygoid muscle (along with the masseter muscle) has been shown to be significantly larger compared with the controls, suggesting that hyperactivity of these muscles can be a factor in patients with this diagnosis.³³ Interestingly, no changes

in the thickness of the medial pterygoid (or masseter and temporalis) muscle have been seen in patients with rheumatoid arthritis.³⁴ Other literature on how this muscle relates to TMD is limited.

Pain in the teeth or gums could easily be mistaken for a true dental problem if a thorough examination is not done that includes muscle assessment. As mentioned, the medial pterygoid muscle can refer to the teeth and gums^{22,23} and should be considered in the differential diagnosis, especially if a dental examination does not show carious lesions or inflammation of the gums.

The medial pterygoid muscle can be a site of entrapment of the lingual nerve that can penetrate the muscle^{2,35} and become entrapped between the medial pterygoid muscle and an ossified pterygospinous ligament.^{36,37} If entrapped, symptoms such as altered sensation to the floor of the mouth, mucosa, lingual gingiva, and the mucosa of the anterior two thirds of the tongue can occur.³⁸

Trismus is a firm closing of the jaw due to spasm of masticatory muscles that, for example, is characteristic of tetanus. Differential diagnosis of the cause of trismus is essential. Tetanus may also result from dental sepsis, injury, surgery, needle abscess, and the Morgagni syndrome caused by a malignant tumor. As recently as 2012, in a case study by Fusetti et al,³⁹ a 78-year-old farmer was diagnosed with tetanus with progressive onset of lockjaw and muscular stiffness. Furthermore, a 31-year-old patient in another case study who had proper levels of tetanus antibodies was treated for tetanus symptoms after puncturing his hand with a rusty nail.⁴⁰ Trismus can also be due to spasm of the medial pterygoid muscle from cellulitis in the pterygomandibular space, spasm of the masseter muscle from cellulitis in adjacent tissues, or spasm of the temporalis muscle from cellulitis in the infratemporal fossa.⁴¹ Trismus in the medial pterygoid muscle can also occur after an inferior alveolar nerve block.⁴² Attempts to open the jaw are painful and limited because of the spasm. Trigger points can be treated by injection only if there is no evidence of infection in the region to be treated. Mouth-opening exercises, heat, muscle relaxants, and physical therapy are beneficial for treatment of patients for whom injections are not recommended.⁴²

Hypertrophy of the medial pterygoid muscle is a very rare condition that is more often asymptomatic than not. More commonly, the masseter muscle is involved than the medial pterygoid muscle. The most common report with this condition is of facial asymmetry. A recent case report highlights a rare case of hypertrophy of the medial pterygoid and masseter muscles together. The patient reported facial asymmetry from swelling on the posterior lower left tooth region for 4 years.⁴³

Myositis ossificans is a rare condition wherein heterotopic bone forms in muscle or soft tissue, usually after some type of trauma or injury. It is not very common to occur in muscles of the masticatory system. From 2001 to 2014, only 11 cases (of the 20 in the masticatory system) have been reported in the medial pterygoid muscle.⁴⁴ Although rare, this diagnosis should be considered as a possibility if there is loss of jaw range of motion after facial trauma or invasive medical or dental procedures.^{45,46} In addition, this condition

can occur idiopathically, so even without trauma, this condition should be considered in the differential diagnosis.

As stated previously, TrPs in the medial pterygoid muscle can mimic otolaryngic symptoms including sinusitis, hearing changes, ear pain and clogging, throat pain and congestion, and tonsillitis.²³ When diagnostic testing does not yield significant findings for the cause of symptoms, TrPs in the medial pterygoid muscle should be considered.²³

Oromandibular dystonia is a focal neurologic disorder that can affect the face and the jaw. Typically, involuntary facial grimacing and jaw or tongue movements occur. Those with jaw-closing dystonia more frequently have orobuccolingual involvement than those with jaw-opening dystonia.⁴⁷ The cause of the dystonia is more frequently idiopathic,^{48, 49} but can also be secondary to neurologic diseases,^{48, 49} infections,⁴⁹ or antipsychotic drugs.⁵⁰ The masseter and temporalis muscles are the most commonly involved for jaw-closing dystonia/myospasm⁴⁸; however, the medial pterygoid muscle can be involved as well.^{51–53} Knowledge of this condition is essential because it can easily be misdiagnosed as TMD or bruxism.⁴⁸

5. CORRECTIVE ACTIONS

First, because TrPs in the medial pterygoid muscle may develop as a result of dysfunction in other muscles such as the sternocleidomastoid and masseter muscles, these should be addressed first (refer to Chapters 7 and 8).

Forward head posture should be corrected to reduce muscle activity in the medial pterygoid muscle and other jaw elevator muscles. Mouth breathing as compared with nasodiaphragmatic breathing has a negative impact on posture,^{54–59} and should therefore be corrected. Performing strengthening and flexibility exercises in conjunction with nasodiaphragmatic breathing can help improve posture.⁵⁷

Effective resting jaw position (with the tongue on the hard palate behind the top teeth, lips together, and teeth slightly separated) can be helpful to reduce stress on the muscle and minimize open mouth breathing during waking hours and attempts to fall asleep.

Parafunctional habits such as clenching, nail biting, and exhaustive chewing should be identified and discontinued immediately to reduce strain on the medial pterygoid muscle.

If the patient sleeps on the side, proper pillow positioning can prevent increased muscle activity caused by the jaw dropping down to one side during the night. A corner of the pillow should be tucked between the side of the face and the shoulder so that the pillow supports the jaw in a neutral position.

In addition to inactivating masticatory muscle TrPs, bruxism should be identified and treated. Use of an intraoral orthosis may be required. For a more significant benefit, cognitive behavioral therapy concurrent with use of an occlusal splint may be advised.⁶⁰ Conti et al⁶¹ demonstrated that behavioral changes in conjunction with occlusal devices were effective in treating masticatory myofascial pain.

Factors that increase anxiety and emotional stress should be identified and alleviated, if possible. Studies have suggested that those with individuals with depression scores, somatic

complaints, and decreased physical well-being are at a higher risk of suffering symptoms.⁶² Referral to a psychologist or other mental health provider for specific pain and stress management techniques can be very helpful due to the importance of dealing with multiple contributory factors.⁴¹

Figure 10-4. With the patient in a seated or standing position, the jaw is pressed into the fist underneath to activate the muscles that open the jaw. This reciprocally inhibits the medial pterygoid muscle (and other jaw-closing muscles).

Once dysphagia due to TrPs has been resolved, swallowing a tablet or capsule is facilitated by placing the medication underneath the tip of the tongue, behind the lower front teeth, where it can follow the bolus of liquid when the head is erect.⁶³ When the tablet is placed on top of the tongue, as is customary, the tongue presses it against the roof of the mouth where it tends to stick during swallowing.

Resisted jaw-opening is an augmented stretch technique based on reciprocal inhibition (Figure 10-4). Patients are instructed to open the jaw slowly against light resistance of their fist. The activation of the jaw depressors (digastric, suprahyoid, and infrahyoid muscles) inhibits the elevation function of the medial pterygoid muscle (and all other jaw elevators), providing a useful technique for releasing all the jaw elevator muscles simultaneously.

Activation of TrPs during a prolonged dental procedure may be prevented by taking breaks to allow the patient to perform several cycles of active range of motion.

Lateral Pterygoid Muscle

“TMD Disaster”

Michelle Finnegan, Amanda Blackmon, and Joseph M. Donnelly

1. INTRODUCTION

The lateral pterygoid muscle is an important muscle for movement and control of the jaw that is comprised of two divisions: superior and inferior. The superior division of the lateral pterygoid muscle originates from the infratemporal crest and infratemporal surface of the greater wing of the sphenoid bone, while the inferior division of the lateral pterygoid muscle originates from the lateral surface of the lateral pterygoid plate. The two divisions converge to insert onto the pterygoid fovea, a depression on the front of the neck of the mandible. A branch of the buccal nerve innervates the superior division and the lateral part of the inferior division of the lateral pterygoid muscle. The medial part of the inferior division of the lateral pterygoid muscle is innervated by a branch directly from the anterior trunk of the mandibular nerve. The lateral pterygoid muscle receives its vascularization from the pterygoid branches of the maxillary artery. Bilaterally, the muscle functions to open and protrude the mandible, and unilaterally it functions to deviate the mandible to the opposite side. It also assists in approximating the structures of the temporomandibular joint (TMJ) during mouth closing. Trigger points (TrPs) in the lateral pterygoid muscle may refer pain in and around the maxillary sinus and near the TMJ. They can also contribute to increased secretion of the maxillary sinus, tinnitus, and limitations in range of the motion of the TMJ. Trigger points in this muscle are perpetuated by excessive gum chewing, parafunctional habits, strain to the mandible when playing instruments, and by TrPs in cervical muscles that refer to the lateral pterygoid region. Differential diagnosis is of utmost importance due to the variety of symptoms this muscle can engender. This muscle is associated with temporomandibular disorders (TMD), TMD with migraine, infection, nerve entrapments, myositis ossificans, otolaryngic symptoms, and oromandibular dystonia. Corrective actions for the lateral pterygoid muscle include correction of posture, proper tongue and jaw position, elimination of parafunctional habits, nasal breathing, and inactivation of cervical muscle TrPs that refer to the lateral pterygoid muscle.

2. ANATOMIC CONSIDERATIONS

The lateral pterygoid muscle is a short, thick muscle that lies deep into, and largely behind, the zygomatic arch and the coronoid process of the mandible. The superior division of the lateral pterygoid muscle originates from the infratemporal crest and infratemporal surface of the greater wing of the sphenoid bone¹ and travels in an inferior, lateral, and posterior direction toward its insertion.² The inferior division of the lateral pterygoid muscle originates from the lateral surface of the lateral pterygoid plate¹ and travels in an upward, lateral, and posterior direction toward its insertion² (Figures 11-1 and 11-2A). The fibers of the two divisions converge to insert onto the pterygoid fovea, a depression on the front of the neck of the mandible (Figures 11-1 and 11-2A).¹ The insertion for the superior division, however, is controversial. The superior division has been shown to have attachments to the condyle only,² disc–capsule complex only,^{2–5} and to both the disc–capsule complex and the condyle.^{2–5} Of these, the attachments to both the disc–capsule complex and the condyle are the most common and the disc–capsule complex only attachment is the least common. Usui et al⁶ reported different anatomic attachments from others, with fibers of the lateral pterygoid originating from the posterior half of the lateral pterygoid plate inserting onto the medial surface of the condylar process of the mandible. They also found that only a superficial layer of the fibers in the horizontal portion of the muscle originated from the inferior part of the greater wing of the sphenoid and attached to the inferior surface of the disc in all specimens.

Figure 11-1. Anatomy and muscle attachments of the lateral pterygoid muscle. The zygomatic arch and superficial portion of the temporomandibular joint have been removed. Both divisions of the muscle attach to the neck of the mandibular condyle. The condyle normally articulates with the posterior surface of the articular tubercle of the temporal bone in this position until the mouth is opened wide as in a yawn.

Figure 11-2. A, Frontal section of the head (level of cross section shown in B). This view looks forward through the open mouth. The condylar neck of the mandible obscures part of the needle, which penetrates the inferior division of the muscle. The medial pterygoid

muscle (light red) lies in the foreground and attaches to the inner surface of the pterygoid plate. B, Cross section showing the masseter muscle and then the temporalis muscle (light red) as it passes in front of the condylar neck of the mandible above the mandibular notch (level of cross section is shown in A). The needles reach the anterior and posterior portions of the inferior division of the lateral pterygoid muscle (dark red).

In addition to variations in the attachments of this muscle, Sugisaki et al⁷ reported variations in the number of heads of this muscle including one head; three heads; medial and lateral heads; superior and inferior heads; and superior, inferior, and medial heads. Recently, others have also reported the lateral pterygoid muscle having three heads.^{3,8}

Interestingly, an aberrant muscle located between the temporalis and lateral pterygoid muscles named the pterygoideus proprius muscle has also been reported. Akita et al⁹ described this muscle as originating from the medial surface of the anteromedial muscle bundle of the temporalis muscle and running in an inferomedial direction, with one of the specimens also originating from the infratemporal crest of the greater wing of the sphenoid bone. From this origin, the muscle attached to the inferolateral surface of the lower head of the lateral pterygoid muscle in one specimen, and in two specimens the insertion also continued to insert on the inferior margin of the lateral pterygoid plate of the sphenoid bone.

The lateral pterygoid muscle changes its fiber composition with aging. Older adults have a large proportion of type-IIA fibers compared with young adults who rarely, if ever, exhibit this fiber type in the lateral pterygoid muscle.^{10,11} Interestingly, only the inferior division of the muscle showed atrophy with aging.

2.1. Innervation and Vascularization

A branch of the buccal nerve innervates the superior division and the lateral part of the inferior division of the lateral pterygoid muscle. The medial part of the inferior division of the lateral pterygoid muscle is innervated by a branch directly from the anterior trunk of the mandibular nerve.¹ Kim et al reported that the buccal nerve penetrates the inferior lateral pterygoid muscle in 12.5% of cases.¹² This muscle, particularly the inferior division, has several different reported innervation variations including innervation from ansa pterygoidea,¹² anterior deep temporal nerve,^{12,13} and mandibular nerve trunk.¹² Various combinations of the above-listed nerves may innervate the muscle. The superior division can receive innervation from the mandibular nerve trunk (middle deep temporal nerve),^{12,13} anterior deep temporal nerve,^{12,13} and mandibular nerve trunk.¹² A recurrent branch of the inferior alveolar nerve^{14,15} and a branch from the auriculotemporal nerve have been reported to innervate the lateral pterygoid muscle as well,¹⁶ although it was not specific to which division of the muscle.

Vascularization of the lateral pterygoid muscle is supplied by the pterygoid branches of the maxillary artery. These branches are given off as the artery crosses the muscle, and from the ascending palatine branch of the facial artery.¹ The artery frequently courses superficial

to the inferior division of the lateral pterygoid muscle, and less often it courses deep to the inferior division.^{17,18}

2.2. Function

The function of the lateral pterygoid muscle remains controversial in the literature. Some investigators believe that the lateral pterygoid muscle is two distinctly different muscles with very unique actions¹⁹ whereas others think the muscle is made up of two heads that have alternating functions at different times during mouth opening, closing, and chewing.^{20,21} Most authors agree that the primary function of the lateral pterygoid muscle is that of mandibular depression (mouth opening) and contralateral excursion (lateral deviation), especially during chewing.^{1,22,23}

Classically, the function of the inferior head of the lateral pterygoid (IHLP) muscle includes mandibular depression (mouth opening) and protrusion of the mandible with the muscles on both sides acting together, and lateral deviation of the mandible to the opposite side by one muscle acting unilaterally (contralateral excursion).^{1,20} The superior head of the lateral pterygoid (SHLP) muscle is active during mandibular elevation (mouth closing), retrusion, and ipsilateral excursion. Other functions of the SHLP muscle were to decrease tension in the disc by contracting eccentrically during mouth closing, keeping the disc positioned beneath the condyle by creating a forward tension on the disc and neck of the mandible.²⁰

Electromyographic (EMG) studies utilizing computerized tomography and functional magnetic resonance imaging (MRI) have provided evidence for functional heterogeneity in both the SHLP and IHLP muscles.²⁰ Functional heterogeneity is described as the ability of different regions in a muscle to exhibit different actions during the same task.²¹ Electromyographic activity of single motor units was recorded from multiple sites in the SHLP and IHLP muscles, and was then confirmed with computerized tomography. The EMG data from the SHLP muscle shows that it has an important role in mandibular depression (mouth opening), contralateral excursion, and protrusion of the mandible.^{21,24} The EMG data for the IHLP muscle are consistent with the classical description of its function in mandibular depression (mouth opening), contralateral excursion, and protrusion of the mandible.²³⁻²⁶

Ipsilaterally, the medial pterygoid and both divisions of the lateral pterygoid muscles, along with the contralateral masseter and temporalis muscles, participate in the lateral and closing movements of the jaw during grinding of food between the molar teeth.²⁷

The lateral pterygoid muscle contributes to the creation and fine motor control of mandibular forces in protrusion and contralateral excursion.²⁸ Electromyographic studies investigating the function of the lateral pterygoid muscle²³⁻²⁶ indicate a complex physiology with multifaceted muscle activation patterns in the layers of the SHLP and IHLP muscles during mastication. This may be attributed to selective sequencing of single motor units as a result of central pattern generators highlighting the role of the reticular formation in oral function.²²

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 11-1 grossly represents the functional unit of the lateral pterygoid muscle.²⁹

Box 11-1 Functional unit of the lateral pterygoid muscle

Action	Synergists	Antagonist
Mandibular depression	Digastric Suprahyoid muscles Contralateral lateral pterygoid	Masseter (bilaterally) Temporalis (bilaterally) Medial pterygoid (bilaterally)
Mandibular protrusion	Contralateral lateral pterygoid Medial pterygoid (bilaterally)	Temporalis Deep head of the masseter
Mandibular lateral deviation	Contralateral lateral pterygoid Contralateral medial pterygoid Ipsilateral temporalis Ipsilateral masseter	Ipsilateral lateral pterygoid Ipsilateral medial pterygoid Contralateral temporalis

Despite the variation in the literature regarding the specific functions of each part of the lateral pterygoid muscle, in general the lateral pterygoid muscle plays a role in mouth opening, protrusion, and lateral deviation of the jaw. The temporalis muscle is active during protrusion, although it does not fire as strongly as with retrusion.³⁰ For chewing food on one side, the ipsilateral masseter, ipsilateral medial pterygoid, and contralateral lateral pterygoid muscles work synergistically with each other.²⁷

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

To date, no distinction between the pain patterns of the two divisions of this muscle have been recorded. The lateral pterygoid muscle refers pain deep into the TMJ and to the region of the maxillary sinus (Figure 11-3).³¹⁻³³ Injections of hypertonic saline into the lateral pterygoid muscle refer pain throughout the entire lateral mandibule, cheek, ear, and anterior temporal regions, with pain described as shooting, boring, sharp, pressing, hot, aching, taut, intense, spreading, and tight.³⁴ Interestingly, Svensson et al³⁴ also reported

referred pain to the teeth and gingiva from the lateral pterygoid muscle, although this was not observed by Simons et al.²⁹ Teachey³⁵ reported similar findings of the lateral pterygoid muscle referring pain to the teeth and gums. Teachey³⁵ also described multiple otolaryngic symptoms related to TrPs in the lateral pterygoid muscle, which is described below.

Figure 11-3. The referred pain pattern (dark red) of TrPs in the left lateral pterygoid muscle (pink).

Simons et al.²⁹ believe that TrPs in this muscle are the chief myofascial source of referred pain felt in the TMJ area. The myofascial pain syndrome is easily mistaken for the pain of TMJ arthritis.³⁶

3.2. Symptoms

Patients with TrPs in the lateral pterygoid muscle often describe pain in the maxillary area as “sinus pain.” They report frequent or recurrent “sinusitis,” however, the pain does not respond to medications. Chronic or recurrent throat and/or neck symptoms including discomfort/drainage/congestion, sore throat, and “tonsillitis,” may be reported as well as nasal obstruction, nasal congestion, nasal pressure, ear pain, and clogging.³⁵ As a result, patients may think that they are sick when they are not, and they may be prescribed unnecessary medications.

Patients with normal otolaryngic studies, including an audiometric evaluation, who have changes in hearing including either increased sensitivity to sounds (hyperacusis) or slight decreased sensitivity to sounds (hypoacusis), or even hearing loss may have TrPs in the lateral (or medial) pterygoid muscle.³⁵

A burning sensation in the throat or mouth may also be reported by patients who have TrPs in the lateral pterygoid muscle.³⁵

Because the lateral pterygoid muscle can refer to the TMJ, patients often report that

their “jaw hurts.” Severe pain in the TMJ region is commonly referred from TrPs not only in the lateral pterygoid muscle, but also the medial pterygoid muscle or the deep layer of the masseter muscle.

Loss of jaw movement or difficulty with jaw movement is common,^{37,38} as well as reports of “stiffness” that can resultantly contribute to patients having difficulty eating foods that require wide mouth opening. In addition to having difficulty opening the mouth when eating, patients may also report difficulty swallowing (dysphagia) or pain with swallowing (odynophagia).³⁵

Patients may report that their teeth do not contact evenly anymore, or their bite “feels different,” oftentimes despite extensive work to the teeth or TMJ, and/or use of appliances.³⁶

Although not common, tinnitus may be due to TrPs in the lateral pterygoid muscle in some patients.^{35,39}

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The clinician should perform a brief examination of the TMJ and should also assess the patient’s posture, with particular attention to head and neck positions. Forward head posture and excessive tension in suprahyoid and infrahyoid muscles should be noted, although the relation between TMD and head and neck posture is still controversial and unclear.⁴⁰

Normal or functional mouth opening can be determined by attempting to place stacked proximal interphalangeal joints of the first two fingers of the nondominant hand between the upper and lower incisor teeth (Figure 8-3, two-knuckle test). Usually, about 2½ knuckles of mouth opening is functional. When the inferior division of the lateral pterygoid muscle is affected, there will likely be a decrease in jaw-opening that prevents the entry of two knuckles between the incisor teeth. Lateral excursion of the mandible is reduced toward the same side because of the increased muscle tension. When the patient slowly opens and closes the jaw, the midline incisal path of the mandible deviates in an S-curve. The most marked deviation from the midline during the movement is usually away from the side of the more affected lateral pterygoid muscle, but this is not a reliable sign because TrP involvement of other masticatory muscles, especially the medial pterygoid muscle, can produce or alter this finding.

A more standardized, objective way to measure mouth opening is with a vertical ruler to measure the distance between the upper and lower incisors.^{41,42} Normal opening for women is 41 to 45 mm and for men is 43 to 45 mm.^{43,44}

3.4. Trigger Point Examination

Of all the masticatory muscles, the lateral pterygoid muscle seems to be the one to most

likely have TrPs. As a result, palpation of this muscle is of utmost importance; however, the specificity and reliability of palpating the lateral pterygoid muscle is controversial. Several authors report it cannot be dependably palpated^{45, 46} because the reliability and validity are so poor⁴⁷⁻⁴⁹; others more recently report that it can be palpated accurately with confirmation through MRI.^{50, 51} Reasons for this extreme difference of opinion are that the space where the finger needs to access part of the lateral pterygoid muscle is reportedly smaller than the average finger,⁴⁵ and even if the finger can access the area, oftentimes what is actually being palpated is part of the superficial head of the medial pterygoid muscle, not the lateral pterygoid muscle.⁴⁵⁻⁴⁷ Even when the superficial medial pterygoid muscle was absent, the lateral pterygoid muscle was only able to be accessed 50% of the time.⁴⁶ Another reason for inaccurate palpation of this muscle is the high percentage of control patients who feel very tender in this region.⁴⁹ More recently, Conti et al⁴⁸ reported similar findings that 66.7% of controls and 79.5% of those with myofascial pain felt tender in this muscle; whereas palpation of other muscles examined, the control group did not feel tender in as many areas. Since this region is painful in a large percentage of controls, patients can be misdiagnosed as experiencing myofascial pain or involvement of the lateral pterygoid muscle.

Despite the controversy in palpating this muscle, the technique that is commonly used to access the region of the lateral pterygoid muscle is described. Clinicians should interpret the information from this palpation technique with caution for reasons stated above. To examine intraorally for TrP tenderness in the region of the anterior attachment of the inferior division of the lateral pterygoid muscle, the mouth is opened about 2 cm (3/4 in) while the index or little finger presses posteriorly as far as possible along the vestibule that forms the roof of the cheek pouch. The finger goes a little past the maxillary tuberosity and the finger should squeeze between the maxilla and the coronoid process as it does this. This area can be small and difficult to move the finger through; lateral deviation of the jaw to the ipsilateral side can be done to increase the space slightly.^{29, 51} Interestingly, others who describe accurate palpation of this muscle do not report using lateral deviation to increase accessibility of this muscle.^{48, 50} Once reaching the softer area behind the maxillary tuberosity, the direction of palpation varies among those who report that the muscle can be palpated. Directions described include the finger pressing medially toward the lateral pterygoid plate²⁹; in a posterior, superior, and medial direction⁴⁸; the finger hooking medially to⁵⁰; or going in a craniomedial direction⁵¹ (Figure 11-4B). Stelzenmueller et al⁵¹ also reported utilizing opening and closing of the mouth with palpation to confirm the location of the muscle.

Figure 11-4. A and B, External and intraoral examination of the left lateral pterygoid muscle. A, External palpation of the posterior part of the muscle bellies of both divisions of the lateral pterygoid through the masseter muscle. The mouth is voluntarily held open by the

patient to relax the masseter muscle and permit palpation through that muscle and through the aperture between the mandibular notch and the zygomatic process (dotted lines). External examination permits indirect palpation for tenderness of the posterior parts of both divisions of the muscle because they approach their attachments to the neck of the condyle inferior to the temporomandibular joint. B, intraoral palpation permits more direct examination of the region of the anterior attachment of the inferior division. With a gloved hand, the operator slips a finger into the uppermost rear corner of the cheek pouch toward the head of the mandible and then presses medially toward the pterygoid plate. The jaws should be open about 5 to 8 mm (about ¼ in) to allow room for the fingertip to squeeze into the space deep to the coronoid process. See text for additional comments regarding examination.

The handle end of a dental mirror or other blunt instrument has been reported by others to substitute for the finger if the space is too restricted,⁴⁵ but this may produce a more concentrated pressure stimulus and may be ineffective for precise identification of structures.

It would be expected with TrPs that this area would be very tender to palpation; however, as stated previously, this area can also be very tender in those who have no pain in the craniofacial region.^{48, 49} With the high incidence of false positives, caution is warranted in using pain with palpation to diagnose TrPs.

Tenderness of temporalis fibers attaching to the medial aspect of the coronoid process, lateral to the palpating finger (or probe), is distinguished from tenderness of lateral pterygoid fibers, medial to the finger (or probe), by the patient's response to the direction of pressure.⁴⁵

It is possible that the posterior attachment region of both divisions is accessible to external palpation at the neck of the mandibular condyle just below the TMJ. Both muscle bellies can, with proper precautions, be examined externally through the masseter muscle for tenderness and referred pain.

Accessing the lateral pterygoid muscle by external palpation has not been confirmed or validated in the literature at this time. Simons et al²⁹ reported the muscle can be palpated, but not if the jaw is closed because the superior division lies deep to the zygomatic arch and the inferior division lies deep to the ramus of the mandible. With the jaw separated about 3 cm (1 1/8 in), a posterior portion of the inferior division and of the superior division may be approached externally through masseter fibers at the opening between the mandibular notch and the zygomatic arch (Figure 11-4A).

Because the lateral pterygoid muscle can only be palpated through the masseter muscle, one should first identify and inactivate any TrPs in the masseter fibers of the area to be examined. When TrP tenderness is present in the masseter muscle, its taut bands are readily palpable, but TrP bands in the underlying lateral pterygoid muscle are too deep to be distinguished by more than their local tenderness and by their referred pain response to pressure. Trigger points in either the temporalis or the masseter muscle can prevent sufficient mouth opening for satisfactory examination of the lateral pterygoid muscle bellies

for tenderness. Unless the temporalis and masseter TrPs are successfully inactivated, only the posterior attachment region can be examined for any involvement.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the lateral pterygoid muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁵² Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. Specifically, excessive gum chewing or parafunctional habits such as bruxism, jaw clenching, nail biting, or persistent thumb-sucking by a child can not only initiate but also perpetuate TrPs in the lateral pterygoid muscle. Excessive chewing on one side contributes to overload in the contralateral lateral pterygoid muscle.²⁷

In addition, playing a wind instrument with the mandible fixed in protrusion or by maintaining mandibular side pressure to hold a violin in playing position can also contribute to the development of TrPs in this muscle.

Lateral pterygoid TrPs may develop in response to TrP activity of the neck muscles, especially the sternocleidomastoid muscle, which, in turn, may be activated by the mechanical stress caused by a leg length discrepancy, a small hemipelvis, or other lower-body postural abnormalities. As a result, TrPs in the lateral pterygoid muscle are not fully resolved until the sternocleidomastoid muscle or other structural impairments are addressed.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.⁵³ Therefore, musculature in the referred pain areas for each muscle should also be considered. Trigger points in the lateral pterygoid muscle can be due to TrPs in the sternocleidomastoid muscle. Additionally, TrPs in the lateral pterygoid muscle can contribute to associated TrPs in other muscles including the masseter, medial pterygoid, orbicularis oculi, and zygomaticus major and minor muscles.

When the inferior division of the lateral pterygoid muscle has TrPs, its antagonists are likely to develop associated TrPs, including the contralateral medial and lateral pterygoid muscles, and ipsilateral deep masseter muscle, and posterior fibers of the temporalis muscle.

4.3. Associated Pathology

Some medical conditions give rise to symptoms that can appear confusingly similar to those produced by lateral pterygoid TrPs or may be present concurrently. Involvement of the lateral pterygoid muscle can be associated with TMJ internal derangements (Chapter 18). Some report that due to the attachment of the lateral pterygoid muscle to the disc, either

completely or partially,^{2–5} it can have an influence on disc dysfunction^{54–56}; others report that it is unlikely.^{3,5,57} Many studies have found lateral pterygoid muscle involvement in patients with TMD.^{37,38,58,59} Patients with TMD and migraine can also have associated involvement of the lateral pterygoid muscle.⁶⁰ Lateral pterygoid TrPs can produce referred pain that is likely to be interpreted as coming from the TMJ. Refer to Chapter 18 for a description of TMJ clinical considerations. The referred tenderness from TrPs has neither the sharp localization nor the intensity of tenderness that is more characteristic of joint inflammation.

The lateral pterygoid muscle can also be a source of potential nerve entrapments; several different anatomic variations of the surrounding nerves have been reported. The auriculotemporal,^{16,61} mandibular,⁶² recurrent branch of the inferior alveolar,¹⁴ inferior alveolar,⁶¹ buccal,¹² lingual,^{61,63–65} and mylohyoid⁶¹ nerves can all pierce through the IHLP muscle, which place the nerve at risk for compression. Only the anterior deep temporal nerve has been shown to pierce through the SHLP muscle.^{13,61} The buccal nerve runs between the two heads of the lateral pterygoid muscle,⁶² which can be a problem if the muscle is hypertrophied and/or in spasm.

The facial pain caused by TrPs from the lateral pterygoid muscle should not be mistakenly diagnosed as the paroxysmal electric-type pain of trigeminal neuralgia, because the symptoms are typically quite different. Ceneviz et al⁶⁶ reported a single case wherein TrPs in the lateral pterygoid muscle did mimic pain features of trigeminal neuralgia and initially met the criteria for a diagnosis of trigeminal neuralgia according to the criteria established by the International Association for the Study of Pain.

Pyomyositis is a rare infection of the striated muscle most frequently observed in the lower extremities. It is a life-threatening condition that, if misdiagnosed, can cause death. Involvement of the lateral pterygoid muscle has been reported, initially presenting with symptoms such as trigeminal neuralgia.⁶⁷ Knowledge of this condition is essential to ensure proper treatment and care.

Myositis ossificans is a rare condition in which heterotopic bone forms in muscle or soft tissue, usually after some type of trauma or injury. It does not commonly occur in muscles of the masticatory system, especially the lateral pterygoid muscle. From 2001 to 2014, only six cases (of the 20 in the masticatory system) occurred in the lateral pterygoid muscle.⁶⁸ Although rare, this diagnosis should be considered as a possibility if there is loss of jaw range of movement after trauma or injections to the face. In addition, this condition can occur idiopathically, even without trauma.

As stated previously, TrPs in the lateral pterygoid muscle can mimic otolaryngic symptoms including sinusitis, hearing changes, throat pain and congestion, and tonsillitis.^{35,69} When diagnostic testing does not yield significant findings for the cause of symptoms, TrPs in the lateral pterygoid muscle should be considered.³⁵

Oromandibular dystonia is a focal neurologic disorder that can affect the face and the jaw. Typical symptoms include involuntary facial grimace, jaw, or tongue movements. The cause of the dystonia is more frequently idiopathic^{70–72} but can also be secondary to

neurologic diseases,^{70,71} infections,⁷¹ or antipsychotic drugs.⁷³ The masseter and temporalis muscles are the most commonly involved, but the lateral pterygoid muscle can be affected as well.^{70–72} Because the lateral pterygoid muscle is significantly deeper than the masseter and temporalis muscles, the diagnosis of lateral pterygoid involvement is more difficult. Three signs and symptoms that are characteristic of this condition include difficulty in jaw-closing after wide opening, jaw function disabilities, and involuntary jaw movements.⁷⁰ Knowledge of this condition is essential because it can easily be misdiagnosed as TMD or bruxism.^{70,72}

5. CORRECTIVE ACTIONS

Excessive forward head posture should be addressed and the patient should be taught correct resting position of the jaw (tongue on the roof of the mouth on the hard palate behind the top teeth, lips together, and teeth slightly separated). The patient should also be instructed in good body mechanics and should learn how to maintain normal head and neck posture. Clenching, gum chewing, nail biting, and other parafunctional jaw habits should be identified and discontinued.

Mouth breathing, as compared with naso-diaphragmatic breathing, has also been shown to have a negative impact on posture^{74–79} and should therefore be corrected. Performing strengthening exercises on an exercise ball and stretches, in conjunction with naso-diaphragmatic breathing, have been shown to improve the posture.⁷⁸

Patients need to learn general neck stretching exercises to help inactivate any TrPs in the cervical muscles such as the sternocleidomastoid muscle that may be perpetuating lateral pterygoid TrPs. In fact, in some patients, TrPs resolve following correction of these two powerful perpetuating factors alone.

Body asymmetry and the resultant functional scoliosis should be corrected by appropriate lifts as this postural stress may activate TrPs in the neck muscles which can cause associated TrPs in the masticatory muscles. If the habit of mouth breathing produces forward head posture, mouth breathing should be corrected by eliminating contributory factors such as nasal obstruction.

The activation of TrPs during a prolonged dental procedure may be prevented by taking breaks for the patient to go through several cycles of active range of movement.

Digastric Muscle and Anterior Neck Muscles

“Tongue Pain Impersonator”

Seth Jason Fibraio, Jennifer Marie Nelson, Simon Vulfsons, Amir Minerbi, and Michelle Finnegan

1. INTRODUCTION

The anterior neck musculature is a dynamic collection of muscles that aid in the overall stability of the neck, participate in head and neck flexion, provide support for swallowing, aid in mastication, and participate in both vocalization and labored ventilation. This group includes the digastric, suprahyoid, infrahyoid, and the anterior vertebral muscles. The suprahyoid muscles are innervated by cranial nerves except for the geniohyoid muscle, which is innervated by C1 through the hypoglossal nerve. This nerve also supplies the thyrohyoid muscle. The ansa cervicalis innervates the sternohyoid, sternothyroid, and omohyoid muscles. The cervical nerves of C1 through C6 supply different parts of the anterior vertebral muscles. These muscles have various functions, including depression of the mandible, movement of the hyoid bone inferiorly and superiorly, and stabilization of the cervical spine. Although this area is not as commonly recognized and treated as a source of pain for craniocervical conditions, it should not be ignored. Trigger points (TrPs) in these muscles contribute to pain in multiple areas, including the anterior neck, larynx, tongue, and lower facial area. Some even refer pain as far as the ipsilateral eye and ear. After trauma and in the presence of pain, the longus colli muscle demonstrates decreased motor activation patterns. Activation and perpetuation of TrPs in the suprahyoid muscles, infrahyoid muscles, and longus colli and longus capitis muscles can be caused by trauma, such as those sustained in motor vehicle accidents, or mechanical trauma, such as choking or blunt trauma, or habitually poor posture. Differential diagnosis of this region is essential to rule out conditions such as infections or malignancies involving the cervical region, dystonia, Eagle syndrome, retropharyngeal calcific tendinitis, intramuscular hemangiomas, myositis ossificans, blood vessel entrapment, omohyoid muscle syndrome, and sternohyoid muscle syndrome. Corrective actions include correction of forward head posture and

instruction in the resting position of the tongue. Instruction in good body mechanics and ergonomics is essential along with TrP self-pressure release and self-stretch exercises.

2. ANATOMIC CONSIDERATIONS

Digastric Muscle

The digastric muscle is one of the suprahyoid muscles comprised of two bellies. The posterior belly of the digastric muscle is longer than the anterior belly and arises from the mastoid notch of the mastoid process of the temporal bone (Figure 12-1). It is deep to the attachments of the longissimus capitis, splenius capitis, and sternocleidomastoid muscles. The anterior belly arises from the digastric fossa at the base of the mandible, close to its symphysis. The anterior belly travels posteriorly and inferiorly toward the hyoid; the posterior belly passes anteriorly and inferiorly to be united end-to-end by a common tendon that usually attaches indirectly to the hyoid bone (at the greater cornu) through a fibrous loop or sling, called the suprahyoid aponeurosis.¹⁻³ In some cases, the tendon can be lined by a synovial sheath or may lack an intermediate tendon. The common tendon may slide through the fibrous loop.^{1,4} The tendon common to the two bellies of the digastric muscle perforates the stylohyoid muscle, which lies near the front half of the posterior belly of the digastric muscle.^{2,5}

Figure 12-1. Attachments of the digastric muscle. A, Side view. B, Front view. The posterior belly attaches superiorly to the mastoid notch and inferiorly, at the muscle's common tendon, by fascial expansion indirectly to the hyoid bone. The anterior belly attaches superiorly to the mandible at the point of the chin and inferiorly, at the common tendon, by fascial expansion indirectly to the hyoid bone.

Anatomic variations of the anterior belly of the digastric muscle have been reported in the literature including atypical fibers,⁵ bilateral superficial and deep heads of the muscle with associated accessory heads of the muscle arranged in a weave pattern,⁶ and accessory heads fusing at midline without a weave pattern.⁷

Suprahyoid Muscles

The other suprahyoid muscles (Figure 12-2) include the stylohyoid, mylohyoid, geniohyoid, and hyoglossus muscles, all of which have their inferior attachment directly to the hyoid bone. The stylohyoid muscle attaches distally to the greater cornu of the hyoid bone¹ and attaches proximally to the styloid process of the temporal bone. The mylohyoid muscle attaches distally to the anterior lower border of hyoid bone and median raphe³ and proximally to the entire length of the mylohyoid line of the mandible. The geniohyoid muscle attaches distally to the anterior surface of the body of the hyoid and proximally deep to the mylohyoid muscle at the inferior mental spine at the back of the symphysis menti.^{1,2} Distally, the hyoglossus muscle attaches along the entire length of the inferior border of the hyoid bone over the greater cornu. It then passes almost vertically upward and enters the side of the tongue.^{1,2}

Figure 12-2. Relatively superficial muscles of the anterior neck including the suprahyoid and infrahyoid muscle groups. On the right side of the body, several of the most superficial muscles (the sternocleidomastoid, sternohyoid, and trapezius) have been removed. Reprinted with permission from Clemente CD. *Gray's Anatomy*. 30th ed. Philadelphia, PA: Lea & Febiger; 1985.

Infrahyoid Muscles

The infrahyoid muscles (Figure 12-2) include the sternohyoid, thyrohyoid, sternothyroid, and omohyoid muscles, all of which have their proximal attachment to the hyoid bone, except the sternothyroid muscle. The sternohyoid muscle attaches to the posterior surface of the medial end of the clavicle, posterior sternoclavicular ligament, and upper posterior aspect of the manubrium distally. Proximally, it attaches to the inferior border of the hyoid bone on the posterior surface.^{1, 2, 8}

The thyrohyoid muscle attaches distally to the oblique line on the lamina of the thyroid cartilage. It then passes upward, attaching along two-thirds of the lower border of the greater cornu of the hyoid bone.^{1, 2, 8} This muscle has been regarded as a continuation of the sternothyroid muscle.¹

The sternothyroid muscle attaches proximally to the oblique line of the thyroid cartilage. Inferiorly, it attaches to the sternum at the posterior surface of the manubrium^{1, 3} and to the posterior edge of the cartilage of the first rib.¹ It forms a continuum with the thyrohyoid muscle and lies deep and medial to the sternohyoid muscle.^{1, 8}

Finally, the omohyoid muscle has two bellies, superior and inferior. The superior belly

attaches to the transverse process of C6, anterior to the scalenus medius muscle.^{1,9} The inferior belly of the omohyoid muscle is separated from the superior belly by a central tendon (held in place by the deep cervical fascia; Figure 12-2). It attaches proximally on the hyoid bone near the border between the body and the greater cornu^{2,3}; distally it attaches to the cranial border of the scapula near the scapular notch.^{1,3,8} As the inferior belly passes forward and up to its attachment to the central tendon, it attaches to the clavicle by a fibrous expansion and passes diagonally over the middle and anterior scalene muscles but deep to the sternocleidomastoid muscle. The central tendon is held in position by a fibrous expansion of the deep cervical fascia that is prolonged caudally to attach to the clavicle and the first rib. From this attachment, the superior belly angles upward to attach to the hyoid bone (Figures 12-2 and 20-7).^{1,2} There are three types of attachments of the omohyoid muscle according to its relationship with the sternohyoid muscle. In type 1, the muscle bundle is adjacent to the sternohyoid muscle, in type 2, it enters the sternohyoid muscle, and in type 3, the omohyoid muscle covers the sternohyoid muscle.² Anatomic anomalies of the omohyoid muscle have been reported, including the inferior belly of the omohyoid muscle originating directly from the clavicle, the superior belly merging with the stylohyoid muscle, and the presence of a double omohyoid muscle.⁹

Anterior Vertebral Muscles

The deeply placed anterior vertebral muscles are comprised of the longus colli, longus capitis, rectus capitis anterior, and rectus capitis lateralis muscles. They are situated along the anterior surface of the vertebral column (Figure 12-3) and lie directly deep to the posterior wall of the pharynx. The longus colli muscle is divided into three parts, a superior oblique portion, an inferior oblique portion, and a vertical portion. The inferior oblique portion arises from the 1st, 2nd, or 3rd thoracic vertebrae, ascends obliquely in a lateral inclination, and attaches to the anterior tubercles of the transverse process of the 5th and 6th cervical vertebrae. The superior oblique portion arises anteriorly from the transverse process of the 3rd, 4th, or 5th cervical vertebrae, ascends obliquely in a medial inclination, and attaches to the anterolateral surface of the anterior arch of the atlas.¹ The vertical intermediate portion arises from the body of the upper three thoracic and lower three cervical vertebrae and attaches to the body of the 2nd, 3rd, and 4th cervical vertebrae.^{1,8} The average cross-sectional area of the longus colli muscle is 0.56 cm² (± 0.12 cm).¹⁰

Figure 12-3. The deepest muscles of the anterior neck including the anterior and lateral vertebral muscles. Reprinted with permission from Clemente CD. *Gray's Anatomy*. 30th ed. Philadelphia, PA: Lea & Febiger; 1985.

The longus capitis muscle is more lateral than the longus colli muscle, extending upward from the anterior tubercles of the transverse processes of C3-C6 to the basilar part of the occipital bone.^{1,8}

The rectus capitis anterior muscle lies deep to the upper portion of the longus capitis muscle and passes upward and slightly medially from the lateral mass of the atlas to the basilar part of the occipital bone in front of the foramen magnum.^{1,8}

The rectus capitis lateralis muscle arises from the superior surface of the transverse process of the atlas and angles laterally and upward to the lateral part of the jugular process

of the occipital bone (Figure 12-3).^{1,8}

2.1. Innervation and Vascularization

The geniohyoid muscle is innervated by C1 through the hypo-glossal nerve.³ All of the remaining suprahyoid muscles are innervated by cranial nerves. The mylohyoid muscle and the anterior belly of the digastric muscle are supplied by the mylohyoid nerve, a branch of the inferior alveolar nerve originating from the trigeminal (fifth cranial) nerve.^{3,11} The stylohyoid muscle and the posterior belly of the digastric muscle are innervated by the facial (seventh cranial) nerve, which exits the skull through the stylomastoid foramen, close to where these muscles attach to the skull.¹ The hyoglossus muscle is innervated by the hypoglossal nerve.¹

The ansa cervicalis nerves, which are derived from the first, second, and third cervical nerves, supply three of the infrahyoid muscles: the sternohyoid, sternothyroid, and both bellies of the omohyoid muscle.^{3,12} The thyrohyoid muscle is innervated by fibers from the first cervical nerve via the hypoglossal nerve.¹²

The rectus capitis anterior and rectus capitis lateralis muscles are innervated by branches from a communicating loop formed between the first and second cervical nerves.^{1,13} A secondary innervation for the rectus capitis lateralis and rectus capitis anterior muscles via the hypoglossal nerve has been reported.¹⁴ The longus capitis muscle is innervated by the cervical ventral rami of C1, C2, and C3.^{1,13} The longus colli muscle is innervated by the ventral rami of the second through sixth cervical nerves.^{1,13}

The anterior digastric muscle receives its vascular supply via the submental branch of the facial artery; the posterior belly of the digastric muscle receives its blood supply via the posterior auricular and occipital arteries.^{1,3} The vascular supply of the geniohyoid muscle is the lingual artery.^{1,15} The stylohyoid muscle receives its blood supply from branches of the occipital, posterior auricular, and facial arteries.¹ The sublingual branch of the lingual artery, the maxillary artery via the mylohyoid branch of the inferior alveolar artery, and the submental branch of the facial artery supply the mylohyoid muscle.¹ The sublingual branch of the lingual artery and the submental branch of the facial artery supply the hyoglossus muscle.¹

For the infrahyoid muscles, the sternohyoid muscle receives its blood supply from the superior thyroid artery, whereas the sternothyroid, omohyoid, and thyrohyoid muscles receive their vascular supply from both the superior thyroid and lingual arteries.^{1,3}

The longus colli muscle receives its vascular supply from the inferior thyroid, ascending pharyngeal, and vertebral arteries.¹ The longus capitis muscle is supplied by the ascending pharyngeal, the ascending cervical branch of the inferior thyroid, and the vertebral arteries.¹ The rectus capitis lateralis muscle receives its vascular supply from the occipital, vertebral, and ascending pharyngeal arteries, whereas the rectus capitis anterior muscle receives its vascular supply from the vertebral and ascending pharyngeal arteries.¹

2.2. Function

Suprahyoid Muscles

The suprahyoid muscles are involved with jaw opening and are adapted mainly for velocity and displacement.¹⁶ All four of the suprahyoid muscles (Figure 12-2) characteristically function in pairs and as a group to open the mouth.¹⁷ They also work together to fix and elevate the tongue, hyoid bone, and thyroid cartilage¹⁸ and are essential for swallowing.¹⁹

The digastric muscle functions with mandibular movements as well as with deglutition. The right and left digastric muscles nearly always contract together, not independently.²⁰ Together, the digastric muscles work to depress the mandible.^{1,4} According to Basmajian and Deluca,²⁰ the anterior belly of the digastric muscle follows that of the inferior belly of the lateral pterygoid muscle. Although the digastric muscle appears to be less important than the lateral pterygoid muscle for initial opening of the jaw, it is essential for maximal depression or forced opening.²⁰ It is the posterior belly of the digastric muscle that is mainly active during jaw opening.²¹ It works closely together with the stylohyoid muscle to open the mouth, but it can only be effective if the infrahyoid muscles contract and stabilize the position of the hyoid bone. Digastric muscle activity is inhibited during depression of the mandible if the mandible is protruded at the same time, which would be expected because of the retraction function of the muscle.

Contracting together, both digastric muscles retract the mandible^{1,4,22} and elevate the hyoid bone.^{1,4} During deglutition, the posterior and anterior bellies of the digastric muscle contract together to translate force to the hyoid bone, causing it to elevate.²³ It has been shown that coughing, swallowing, and retrusion of the mandible strongly recruit the digastric muscles,^{20,24} but it may be the posterior belly of the digastric muscle that assists in oropharyngeal swallowing.²¹

Compared with other muscles of the jaw, the two bellies of the digastric muscle are unusual. The anterior and posterior bellies of the digastric muscle are practically devoid of muscle spindles.^{25,26} The lack of muscle spindles in the jaw-opening muscles and the lack of evidence for control of the digastric muscle by the jaw-closing proprioceptors²⁷ suggest that functionally the jaw-opening muscles do not have a requirement for fine position control. The two bellies of the digastric muscle also have a low percentage of Type I fibers as compared with other muscles.²⁸ The anterior belly of the digastric muscle comprises a large number of Type IIX fibers, whereas the posterior belly comprises a greater number of Type IIA fibers.²⁹

The stylohyoid muscle works to elevate and draw the hyoid bone backward, thereby elongating the floor of the mouth.¹

The mylohyoid muscle raises the floor of the mouth during swallowing, and is active with mastication, sucking, and blowing. It elevates the hyoid bone anteriorly and superiorly and depresses the mandible.^{1,23,30}

The geniohyoid muscle elevates the hyoid bone and draws it forward together with the

digastric muscle.^{1,20,23} It can also assist in retraction of the mandible, depression of the mandible, and protrusion of the tongue.^{1,31}

As a group, the suprahyoid muscles have a larger percentage of Type IIA and IIX fibers (~57%) versus Type I fibers (34.7%). This difference in fibers is well adapted for the phasic activity needed for this muscle group.³²

Infrahyoid Muscles

As a group, these muscles characteristically function in pairs to exert the essential depressive force on the hyoid bone that is required for the suprahyoid muscles to function normally. The omohyoid, sternothyroid, and sternohyoid muscles depress the larynx after it has been elevated during swallowing or vocal movements, whereas the thyrohyoid muscle elevates the larynx if the hyoid is fixed.¹ The sternohyoid and thyrohyoid muscles form a continuous unit (Figure 12-2) to depress the hyoid bone. The greatest intensity of contraction in the cricothyroid muscle occurs in swallowing.¹ Bilaterally, the omohyoid muscles are thought to be involved in prolonged inspiratory efforts because they tense the lower part of the cervical fascia and lessen the inward suction of soft parts.¹ The superior belly of the omohyoid muscle is also involved in movements of the tongue including placement of the tip of the tongue on soft and hard palates, placement of the tongue on the floor of the mouth, protrusion, and right and left lateral movements.³³

When swallowing liquids, the anterior belly of the digastric, masseter, and geniohyoid muscles contracts together, whereas when swallowing solids, the masseter muscle contracts first, followed by the anterior belly of the digastric and geniohyoid muscles. When swallowing both solids and liquids, the sternohyoid muscle contracts last.³⁴ The geniohyoid muscle is primarily responsible for the anterior movement of the hyoid.¹⁹

The muscle fibers of the infrahyoid muscle group are similar to the suprahyoid muscles in that they are designed more for phasic activity, but the makeup of fiber type is slightly different, with approximately 47% of Type II (A and X fibers) versus 40.8% of Type I fibers.³²

Anterior Vertebral Muscles

The anterior cervical muscles typically work in pairs to flex all or part of the neck. All portions of the longus colli muscle contribute to neck flexion. The oblique portion also contributes to ipsilateral lateral flexion and the inferior oblique portion rotates the neck to the contralateral side.¹ The longus capitis muscle flexes the head, whereas the rectus capitis lateralis muscle primarily tilts the head ipsilaterally. The rectus capitis anterior muscle flexes the head but does not contribute to ipsilateral tilting of the head. Both the rectus capitis lateralis and the rectus capitis anterior muscles assist in stabilization of the atlanto-occipital joint because of their fibers angling in opposite directions.¹

The anterior vertebral muscles are thought to be postural in nature; however, recent evidence suggests that the longus colli and longus capitis muscles have both a postural and a

phasic role. In elderly women, the average type 1 fiber was found to be 64.3% in the longus capitis and 55.7% in the longus colli muscle.³⁵ In elderly men, the longus capitis muscle had an average of 48.5% type 1 fibers and the longus colli muscle had 50%.³⁶ These percentages are notably lower than other known muscles that are tonic in nature, indicating both a tonic role as neck postural stabilizers and a phasic one as neck and head flexors.^{37, 38} The question whether these muscles are predominantly phasic or tonic is still debated.³⁹

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter their actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 12-1 grossly represents the functional unit of the digastric and other anterior neck muscles.⁴⁰

Box 12-1 Functional unit of the digastric and other anterior neck muscles

Action	Synergists	Antagonist
Mandibular depression	Lateral pterygoid Stylohyoid Mylohyoid Geniohyoid	Masseter Temporalis Medial pterygoid
Mandibular retrusion	Masseter (deep portion) Temporalis	Lateral pterygoid Medial pterygoid
Hyoid elevation	Geniohyoid Mylohyoid Digastric (anterior belly)	Sternohyoid Sternothyroid Thyrohyoid Omohyoid
Head and neck flexion	Longus colli Longus capitis Rectus capitis anterior Sternocleidomastoid Hyoid muscles	Semispinalis capitis Semispinalis cervicis Splenii capitis Splenii cervicis Cervical multifidi Rectus capitis posterior major Rectus capitis posterior minor

During mandibular depression, the infrahyoid muscles work to stabilize the hyoid

bone.⁴¹ The temporalis muscle, although a synergist for protrusion, is recruited more strongly with retrusion.⁴²

3. CLINICAL PRESENTATIONS

3.1. Referred Pain Pattern

Digastric

There are distinctly different referred pain patterns for the two bellies of the digastric muscle. Trigger points in the posterior belly of the digastric muscle frequently refer pain into the upper portion of the sternocleidomastoid muscle⁴³ and to a lesser extent to the throat, under the chin, and the occiput^{44, 45} (Figure 12-4A, B). The pain referred to the sternocleidomastoid muscle is sometimes mistaken as originating from that muscle, but when the sternocleidomastoid muscle is cleared of TrPs, the pain persists. The occipital component of pain is likely to be associated with referred “soreness” and tenderness. Trigger points in the posterior belly of the digastric muscle have also been shown to refer pain into the forehead, periorbital area, temple, postauricular area, ear, temporomandibular joint, cheek, mandibular teeth, and throat.^{46–49}

Figure 12-4. Referred pain patterns of TrPs in the digastric and longus colli muscles. A and B, Posterior belly of the digastric muscle. C, Anterior belly of the digastric muscle. D, Longus colli muscle, anterior view. E, Longus colli muscle, posterior view.

Pain from TrPs in the anterior belly of the digastric muscle refers to the lower four incisor teeth (along the mandible), to the alveolar ridge below them (Figure 12-4C), and also to the tongue.^{45,47,50} Pain from this belly may also refer to the periorbital area, temporomandibular joint, and cheek area.⁴⁷⁻⁴⁹

Clinically, this muscle has also been seen to refer pain along the mandible up toward the temporomandibular joint. Frequently, the TrPs are located in the muscle just under the tip of the chin and can be on either the left or the right side (Figure 12-4C).

Longus Colli

Pain referral patterns of the longus colli muscle have been explored in healthy individuals.⁵¹ Eliciting pain in the longus colli muscle by either dry-needling or manual stimulation of the muscle provokes local pain mainly in the anterior cervical area (Figure 12-4D). Some

patients report pain being referred to the posterior ipsilateral neck and around the ipsilateral ear and eye (Figure 12-4E). Interestingly, in some patients, pain originating in the longus colli muscle is referred to the contralateral anterior neck. Although being rather unusual, such contralateral referral has also been described in the adjacent sternocleidomastoid muscle (Figure 12-4D).

Other Anterior Cervical Musculature

The mylohyoid muscle can refer pain to the tongue.⁵⁰ In clinical practice, this muscle has also been seen to refer to the ipsilateral occipital region. Head and neck pain from the stylohyoid muscle is closely related to that arising from the posterior belly of the digastric muscle.⁵² These two muscles lie close together, have similar functions, are difficult to distinguish by palpation, and are presumed to have similar pain patterns.

The specific pain patterns of the remaining deep anterior neck muscles are not reported in the literature.⁵¹ However, it has been demonstrated that the longus capitis and longus colli muscles have decreased activity when active nociception is present.⁵³ These muscles can refer pain to the laryngeal region, anterior neck, and sometimes into the mouth region.

3.2. Symptoms

It is hypothesized that unresolved posterior neck pain might result from sustained TrPs of the anterior neck muscles and tightening of their fasciae. If a patient has posterior digastric TrPs, the primary report may not be of pain but of difficulty swallowing, a sensation of a lump in the throat, and/or something being stuck in the throat and not going down. The patient is likely to palpate or point to the sternocleidomastoid muscle on the involved side. Although head rotation range of motion may not be reduced, the patient is likely to avoid turning the head to the involved side because the movement will elicit referred pain or aggravate the swallowing problem. The posterior digastric muscle referred pain pattern, as shown in Figure 12-4A, concentrates in the region of the superior part of the sternocleidomastoid muscle, as well as the cheek (closer to the angle of the mandible) and ear.⁴⁵ As a result of the overlap of the digastric muscle referred pain with other areas, the patient may not become aware of the digastric muscle referred pain component until after concurrent sternocleidomastoid TrPs on the same side have been inactivated, and the pain in that region still persists. This development can be very perplexing to the clinician unless the possibility of posterior digastric TrPs is investigated.

The chief symptom from TrPs in the anterior belly of the digastric muscle is pain in the region of the lower incisor teeth. The source of this tooth pain can also be confusing if the clinician considers only the teeth as the source of pain and does not consider the anterior digastric muscle. Patients with TrPs in the anterior digastric muscle may also report pain in the cheek and temporomandibular joint.⁴⁵

There are no specific pain referral patterns reported in the literature for the omohyoid muscle; however, loosening of the intermediate tendon of the omohyoid muscle may lead to pseudodysphagia.⁵⁴ When the omohyoid muscle develops TrPs, it can act as a

constricting band across the brachial plexus.⁵⁵ Adson⁵⁶ relieved pain and dysesthesia resulting from pressure on the brachial plexus because of abnormal tension in the omohyoid muscle by surgically sectioning the muscle. Rask⁵⁷ reported the diagnosis and treatment of four patients whose primary cause of pain was myofascial TrPs in this muscle.

Patients with TrPs in the longus capitis and/or longus colli muscles are likely to report difficulty with swallowing and/or having a lump in the throat. Patients with centralized posterior cervical pain should also be evaluated for TrPs in the longus colli muscle. When these symptoms occur in a person who has sustained a cervical flexion-extension injury (“whiplash”) from a rear-end motor vehicle accident or any other head/neck trauma, longus colli TrPs are likely to be a contributing factor. Rocabado and Iglarsh⁵⁸ reported that patients with a “spasm” in the longus colli muscle reported symptoms of a dry mouth, a sore throat without infection, a persistent tickle in the throat, or a lump in the throat with swallowing. Further, recent studies that demonstrate an increase in fatty infiltrates of the longus colli and longus capitis muscles after whiplash injury may be a contributor of neck pain.⁵⁹ In cases of patients with temporomandibular dysfunction, vertical mandibular opening can be reduced in patients with decreased deep cervical flexor strength.⁶⁰

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Cervical range of motion assessment should include measurements in each direction and observation of the quality of motion, which can assist in determining range of motion restrictions at the atlanto-occipital and atlanto-axial region, mid and lower cervical spine. Any deviations in cervical flexion or extension, as well as any changes in C curvature into lateral flexion need to be further evaluated with assessment of the surrounding soft tissue and joint accessory mobility. A shortened longus colli muscle may present as a straightening of the physiologic cervical lordosis. Joint mobility and range of motion of the thoracic spine should also be examined.

The hyoid bone is a very important structure to evaluate as it may influence the curvature of the cervical spine,⁶¹ movements of the mandible, swallowing, and sound formation in speech.⁵⁸ Trigger points in the suprahyoid and/or infrahyoid muscles can influence the position of the hyoid, creating dysfunction in the anterior neck musculature. The easiest and most clinically applicable way to evaluate the hyoid bone is with the clinician manually assessing the hyoid for free movement laterally in both directions. The hyoid can also be assessed with a cephalometric examination technique looking at the hyoid triangle.⁶² With this measurement three lines are drawn: one from C3 to the most inferior/posterior portion of the symphysis menti (retrognathion, RGN), one from C3 to the hyoid, and one from the hyoid to the RGN. A normal vertical position of hyoid bone is below the line of the C3 and RGN.

Recognition of muscle balance is always important, especially between the suprahyoid

and infrahyoid muscles because the hyoid bone is “floating” between them. The concept of inhibited and facilitated muscles contributing to imbalance⁶³ is widely accepted. The digastric muscle has been identified as being prone to weakness and inhibition⁶⁴; as a result, this can have an effect on the antagonistic muscles, other suprahyoid muscles, and infrahyoid muscles.

Examination of the strength of the longus capitis and longus colli muscles is critical for all cervical spine and/or temporomandibular disorders. Research has demonstrated a high correlation between impaired activation of these muscles and neck pain, as well as impaired postural endurance.^{65–67} The craniocervical flexion test assesses the strength of the longus colli, longus capitis, rectus capitis lateralis, and rectus capitis anterior muscles. This test has been shown to have moderate to good interrater reliability and good to excellent intrarater reliability.^{68, 69} The test has the patient perform a chin tuck and lift the head about 2.5 cm off the plinth. The patient is timed on how long they can hold the chin tuck position.⁶⁸ The average hold time for women is 38.43 seconds; men have an average hold time of 63.73 seconds.⁶⁸ The test can also be performed using a pressure sensor (blood pressure cuff/Chattanooga stabilizer). The patient starts at 20 mm Hg, holding a cranial nod for 5 to 10 seconds. The pressure is increased by 2 mm Hg (up to 30 mm Hg), with the cranial nod being repeated until the patient cannot perform the test without compensation that may be seen in either a loss of neutral position or increased activation of the scalene and/or sternocleidomastoid muscles.^{70–72}

3.4. Trigger Point Examination

The muscles of the anterior cervical spine are particularly small, making it challenging to palpate for TrPs. A thorough understanding of the anatomy of this area is crucial to ensure the clinician is palpating tissues accurately.

The anterior and posterior bellies of the digastric muscle can be indirectly assessed by feeling for abnormal resistance when the hyoid bone is shifted from side to side. Oftentimes, decreased mobility of the hyoid bone to one side implicates involvement of the digastric muscle on the contralateral side.

The posterior belly of the digastric muscle is specifically examined with the patient supine and the head and chin tipped upward, in order to widen the area for palpation between the neck and the angle of the mandible (Figure 12-5A). The muscle is located behind the angle of the mandible⁷³ and is found by sliding the finger upward toward the ear lobe along the anterior border of the sternocleidomastoid muscle, pressing the finger inward against the underlying neck muscles.⁴⁵ To confirm identification of the muscle, light resistance of jaw opening is applied with the clinician’s nonpalpating hand just under the chin. A thin, soft, rope-like muscle is felt with the contraction. A cross-fiber flat palpation technique with the tip of the finger is then performed to identify TrPs. Initial pressure on TrPs in the posterior belly elicits exquisite local tenderness, and sustained pressure may reproduce the patient’s referred neck and head pain. The anterior belly of the digastric muscle is examined with the patient supine, the head tilted back, and the neck

extended (Figure 12-5B). To identify the muscle, the clinician's finger is placed just beneath the point of the chin on either side medial to the inferior border of the mandible.⁴⁵ Again, light resistance of jaw opening is applied with the clinician's nonpalpating hand just under the chin. Under the palpating finger, a thin, soft, rope-like muscle is felt with the contraction. The muscle is then palpated from the mandible to the hyoid with a cross-fiber flat palpation to identify any TrPs.

Figure 12-5. Examination of the digastric muscle. A, Posterior belly: palpated between the angle of the jaw and the mastoid process, against the underlying neck structures. B, Anterior belly: the head is tilted back and the neck extended, with the jaw closed, to stretch the muscle as it is palpated against the underlying soft tissues, as described in the text. C, Examination of the longus colli muscle using cross-fiber flat palpation.

One test for anterior digastric TrP involvement as a source of lower incisor tooth pain is to ask the patient to pull the corners of the mouth down vigorously enough to tense the anterior neck muscles. This “Anterior Digastric Test” activates the toothache when positive, indicating the likelihood of TrPs in the anterior belly of at least one digastric muscle.

The omohyoid muscle is easily mistaken for the upper trapezius muscle or a scalene muscle because the tense muscle stands out prominently when the head is tilted to the contralateral side. Because of blending of this muscle with other infrahyoid muscles, it is difficult to palpate and distinguish. General tenderness below the hyoid near the greater cornu and along the anterior/medial scalene muscle may be due to TrPs from the omohyoid muscle. If the inferior belly of the omohyoid muscle has a TrP, it can be

mistaken for the anterior scalene muscle, although the two muscles have different fiber directions. The omohyoid muscle is more superficial than the scalene muscles, as it comes out from beneath the sternocleidomastoid muscle, and crosses diagonally over the anterior scalene muscle (see Figure 20-7). It can cross at about the same level as the location where scalene TrPs can be found, depending on which scalene muscle digitation is involved and the position of the head.

Trigger points in the longus capitis muscle can be palpated behind the posterior pharyngeal wall through the open mouth. Trigger points in the longus colli muscle can be palpated by placing the examining finger along the lateral border of the trachea between the sternocleidomastoid muscle and the thyroid cartilage⁵⁸ and slowly advancing it by separating the musculature from the adjacent trachea by gentle rocking and wiggling motions of the finger. When the finger encounters the vertebral column, that region is explored for TrPs with a cross-fiber flat palpation. Another possible approach to palpation of the longus colli muscle is performed with the patient in the supine position; the 2nd and 3rd fingers of the clinician are slid posterior to the sternocleidomastoid and anterior to the easily palpable cervical transverse processes (Figure 12-5C). The muscle is then palpated in a cephalad-caudal direction.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any of the anterior neck muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁷⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. Specifically, bruxing, gum chewing, and mandible retrusion can predispose the digastric muscles to activation of TrPs. Poor stabilization and control of the head and neck when performing abdominal exercises can also put excessive load on the anterior neck muscles.

Flexion-extension injuries, such as those sustained in motor vehicle accidents, or mechanical trauma, such as choking or blunt trauma, can activate TrPs in the suprahyoid, infrahyoid, longus colli, and longus capitis muscles. These injuries are typical in patients who have fallen backward.⁵¹ Furthermore, forward head posture can then perpetuate these TrPs.⁷⁰ It has been demonstrated that the longus capitis and longus colli muscles exhibit larger amounts of fatty infiltrate in patients with whiplash-associated disorders⁵⁹ along with a decrease in muscle activity of the deep neck flexors and an increase in activity in the superficial neck flexors, such as the sternocleidomastoid muscle. Javanshir et al⁷⁵ found that the longus colli muscle exhibited smaller bilateral cross-sectional area in subjects with bilateral chronic neck pain as compared with healthy controls. It is unknown whether the changes are primary or secondary; however, fatty infiltration could be associated with muscle performance impairments,⁷⁶ whereas reduction in cross-sectional area could reduce the proprioception output of the neck flexors and contribute to the perpetuation of

TrPs.^{77,78}

Trigger points may also be activated when the muscle is placed in a shortened or lengthened position for an extended period of time (eg, excessive chin tuck position or forward head posture, respectively). Although it is thought that forward head posture indirectly induces tension in the supra- and infrahyoid muscles, which can create light tensile forces on the mandible,⁷⁹ recent studies report conflicting evidence regarding the activity of the suprahyoid muscles in this position. Song et al⁸⁰ demonstrated decreased EMG activity of the suprahyoid and infrahyoid muscles in those with a forward head posture compared to those with a normal head posture, whereas Ohmure et al⁸¹ demonstrated that EMG activity of the digastric muscles is slightly increased with forward head posture.

Mouth breathing, versus nasal breathing, has also been shown to have a negative impact on posture,^{82–87} which can resultantly contribute to a stretch weakness of the suprahyoid and infrahyoid muscles. Mouth breathing may result from mechanical blockage (such as nasal polyps), structural distortion of the nasal passages (deviated septum), sinusitis, or recurrent allergic rhinitis.

Sustained activation of the posterior belly of the digastric and stylohyoid muscles can overload, and therefore contribute to activation of TrPs in, the antagonistic fibers of the contralateral posterior temporalis muscle and the contralateral deep division of the masseter muscle. Tautness of these antagonists may potentially balance the mandibular deviation induced by the digastric muscles. If the contralateral muscles are cleared of TrPs, the mandible is then free to deviate to the side of the affected posterior belly of the digastric muscle. If deviation is due solely to posterior digastric TrPs, the mandible is pulled over as the jaw starts to separate, but with further opening, it returns to the midline.

4.2. Associated Trigger Points

Trigger points rarely appear in the anterior neck musculature alone. Commonly, patients will also have TrPs in the upper trapezius, temporalis, and semispinalis capitis muscles. Those with jaw pain will also have TrPs in the muscles of mastication and sternocleidomastoid muscle. In Eagle syndrome, because the posterior digastric and stylohyoid muscles are likely to have TrPs, the longus colli muscle will likely be involved. Those with neck pain will commonly have TrPs in the splenius capitis, splenius cervicis, suboccipitals, levator scapulae, sternocleidomastoid, upper trapezius, temporalis, and deep masseter muscles.

Trigger points can develop in the referred pain areas of primary TrPs⁸⁸; therefore, TrPs in the digastric muscle can be due to primary TrPs in other muscles including the platysma, medial pterygoid, trapezius, and sternocleidomastoid muscles. Hong found that primary TrPs in the sternocleidomastoid muscle could induce associated TrPs in the digastric muscle.⁸⁹ Primary TrPs of the posterior digastric muscle may also contribute to associated TrPs in the occipital portion of the occipitofrontalis muscle and/or the sternocleidomastoid muscle.

4.3. Associated Pathology

Some medical conditions give rise to symptoms that can appear confusingly similar to those produced by TrPs of the anterior neck muscles or may be present concurrently. Additionally, several muscles of the anterior neck are susceptible to rare conditions, of which the examining clinician must be aware. One must bear in mind that although myofascial syndrome is a very common source of pain in the cervical area, in a minority of the cases it may be secondary to other pathologic processes, such as malignancy or infection. Secondary myofascial syndrome is common in patients suffering from head and neck tumors or infectious diseases involving the cervical lymph nodes. In patients with cancer, secondary myofascial pain may develop as a consequence of irritation or direct invasion of muscles by the tumor or as an iatrogenic side effect of irradiation, chemotherapy, or surgery.^{90,91}

Dental disease, earaches, and glossodynia may be, or appear to be, a primary medical condition. However, if examination or diagnostic testing does not provide conclusive results, TrPs in the digastric muscles should be considered as a source of the symptoms because they can refer to the teeth, ear, and throat.^{48,49}

Currently, no neurologic entrapments are attributed to TrP activity of the anterior neck musculature; however, Paraskevas et al⁹² found one case where branches from the ansa cervicalis loop perforated the inferior belly of the omohyoid muscle. This could potentially contribute to symptoms associated with entrapment, if restrictions of the omohyoid muscle were present. Evidence of instances of blood vessel entrapment does exist. Loch et al⁹³ reported that among 85 anatomic specimens they found 7 cases of compression of the external carotid artery (in some cases including the posterior auricular artery) solely by the stylohyoid muscle without ossification of the styloid process. The omohyoid muscle has also been noted as a possible cause of internal jugular vein entrapment in two reported cases.^{94,95}

There are two types of benign tumors that have been found in the anterior neck muscles, intramuscular hemangiomas and lipomas. Intramuscular hemangiomas are benign vascular tumors that occur in skeletal muscles. Compared to cutaneous hemangiomas, these are incredibly rare. Of those that occur, however, 13% to 15% develop in the head and neck region.^{96,97} They vary in pain intensity, are nonmobile, nonpulsatile masses that can be difficult to diagnosis, and are best identified by magnetic resonance imaging.⁹⁸ Although they are most commonly seen in the masseter and upper trapezius muscles, a few cases have also been reported in the anterior neck muscles. There have been at least six cases of intramuscular hemangiomas in the digastric muscle^{96,99–103}; two in the mylohyoid muscle^{97,104} and one reported occurrence each in the geniohyoid, sternohyoid, and thyrohyoid muscles.^{105–107} Lipomas are benign soft tissue tumors and have been found in the longus colli muscle at least twice.¹⁰⁸ If needed, these tumors are easily removed surgically.

Treatment for cancer of the head or neck, such as floor of the mouth cancer, can damage or change the tissue quality of the muscles in the anterior neck. Atrophy and soft

tissue fibrosis of the omohyoid, digastric, sternohyoid, and sternothyroid muscles can occur after radiotherapy.¹⁰⁹

Myositis ossificans is a rare condition where heterotopic bone or cartilage forms in muscle tissue after trauma or inflammation.^{110, 111} This condition rarely occurs in the head and neck region, with only 52 reported cases since 1924.¹¹¹ In the head and neck region, the masseter muscle is most commonly affected; however, one case involving the omohyoid muscle after physical trauma and one case involving the platysma muscle after a radical neck dissection have been reported.¹¹⁰

Myositis is benign inflammatory pseudotumor of the skeletal muscles that is painful and can limit movement.¹¹² When found in the upper neck it may also be called retropharyngeal calcific tendinitis.¹¹³ In the anterior neck muscles, it can cause headaches, neck stiffness, and neck pain that can easily mimic TrPs. It is more common to find in the extremities, but Horowitz et al¹¹⁴ found the rate of incidence to be 0.50 cases per 100,000 person-years for retropharyngeal calcific tendinitis of the longus colli muscle. There has also been one case reported in both the mylohyoid and sternohyoid muscles.^{112, 115}

Dystonia is a movement disorder characterized by intermittent or sustained muscle contractions that typically cause repetitive, abnormal movements and/or postures.¹¹⁶ Oromandibular dystonia involves the masticatory, pharyngeal, and lingual muscles. Abnormal movements associated with this condition include jaw-closing, jaw-opening, jaw lateral deviation, or a combination of abnormal movements. The anterior belly of the digastric muscle is commonly involved with the jaw-opening form of oromandibular dystonia.¹¹⁷ Three reported cases of this type of dystonia have been misdiagnosed in the literature as having temporomandibular joint dysfunction.^{118, 119} Hyoid dystonia is a subphenotype of craniocervical dystonia. With this condition, there is visible contraction of the hyoid muscles and inappropriate lowering or elevation of the larynx with speech or at rest. Commonly, it causes changes in speech, dysphagia, and tightness of the anterior neck instead of the typical abnormal movements and postures.¹²⁰ Cervical dystonia is the most common form of a primary focal dystonia.¹²¹ There are several different types of cervical dystonia, of which a few can involve muscles of the anterior cervical spine. Anterocollis causes flexion of the cervical spine.¹²² Although the sternocleidomastoid muscle is most frequently involved,¹²³ recently, the longus colli muscle has also been shown to be involved.^{121, 122, 124} Anterocaput causes flexion of the head, with the longus capitis and longus colli muscles both being involved.¹²² A posterior sagittal shift causes retraction of the chin, a posterior shift of the head in the sagittal plane, and can involve the longus colli and suprahyoid muscles.¹²⁵

Omohyoid muscle syndrome is a rare condition where there is a protruding lateral neck mass when swallowing. Common reports include pseudodysphagia, neck discomfort, cosmetic problems, and concern for malignancy. Possible causes of this syndrome include failure of the omohyoid muscle to lengthen because of muscle fiber degeneration and failure of the facial-retaining mechanism of the muscle.⁵⁴

Sternohyoid muscle syndrome can easily be confused with omohyoid muscle syndrome

because the symptoms are very similar. Only two reported cases of this condition are in the literature, with symptoms including a lateral neck mass with swallowing, dysphagia with pain, and a sensation of a foreign body in the throat without aspiration or choking difficulties. Neck computed tomography confirmed abnormalities of the sternohyoid muscle.¹²⁶

Eagle syndrome is a condition where the styloid process is elongated or there is calcification of the stylohyoid ligament. Signs and symptoms vary greatly but may include pain in the angle of the jaw, tongue pain, glossodynia, dysphagia, odynophagia, dysphonia, a sensation of increased salivation, foreign body sensation in the throat, voice changes, persistent pain radiating to the carotid artery, headache, neck pain, pain with turning of the head, pain radiating to the eye, blurring or decreased vision, ear pain, or vertigo.^{127–130} The symptoms are related to irritation of cranial nerves V,^{127, 130} VII,^{127, 130} IX,^{127, 128, 130} X,^{127–130} XI,^{129, 130} and XII^{128–130} because of their proximity of the styloid process or stylohyoid ligament. Diagnosis of this condition can be performed with intraoral palpation of the styloid process in the tonsillar fossa,^{129–131} as well as three-dimensional computed tomography^{128, 129, 131} or panoramic radiographs.^{129, 130} With this condition, involvement of the posterior belly of the digastric, stylohyoid, mylohyoid, sternocleidomastoid, and longus colli muscles should also be examined because they are commonly involved with this condition and can also contribute to some of the associated symptoms.

Other diagnoses may be present concurrently with digastric or anterior neck TrPs. For the digastric muscle, this may include headaches or temporomandibular joint internal derangements with or without reduction. For the anterior neck muscles, concurrent diagnoses include chronic or mechanical neck pain, tension-type headaches, whiplash-associated disorders, and upper quadrant pain. Trigger points in the splenii muscles have also been associated with these conditions,^{132–137} and because the anterior neck muscles are antagonistic to the splenii muscles, these conditions should also be considered with the anterior neck muscles.

Understanding the clinical presentation of cervical pain is complicated by the similarity of symptoms arising from joint and muscle pathology. Trigger points in the longus colli, longus capitis, rectus capitis anterior, and rectus capitis lateralis muscles can mimic joint restrictions in the upper cervical spine. The interdependence of joint mobility and muscles makes it difficult to determine if it is a primary capsular problem or a muscle problem, but involvement of the upper neck flexors should be considered when range of motion of the upper cervical spine is restricted and/or painful.

5. CORRECTIVE ACTIONS

Similar to the other neck muscles, addressing posture is essential when anterior neck TrPs are present. Forward head posture and tongue position should always be corrected when identified as a problem. Instruction in good body mechanics and ergonomics is also essential (refer Chapter 76).

Care should be taken to find the proper corrective lenses to ensure the patient

maintains a neutral head posture while viewing a digital screen. The use of bifocals or progressive lenses should be discouraged to reduce the repetitive motion used to try and focus on the information on the screen. If two or more computer monitors are being used simultaneously, they should be centered around the user so that the center of the whole viewing area is directly in front of the user instead of one monitor directly in front of the patient and the other to the side. It may also be helpful to angle the screens in a V or U shape to decrease the amount of cervical rotation and eye movement needed to see all screens. Chair size should also be evaluated because most chairs are designed for an average sized man, thereby causing compensations in posture for individuals who are not this size.

Trigger points have been shown to develop with 1 hour of typing,¹³⁸ so short breaks every 20 or 30 minutes could help reduce TrP formation during computer work. Setting an interval timer or starting to integrate a quick stand break whenever a specific routine task is performed, such as answering the phone, can help to increase motion without interrupting the train of thought. Using a footrest or a standing desk can also encourage more movement.

Proper breathing is also important to assist with postural training, decrease bruxism, and help decrease muscle imbalances associated with those who have sleep apnea and dysphasia. Patients should be trained in naso-diaphragmatic breathing instead of mouth breathing because mouth breathing has a negative impact on posture.⁸²⁻⁸⁷ Mouth breathing favors depression and retrusion of the mandible, causing activation and shortening of the digastric muscles. This can lead to malocclusion and an elevated hyoid bone position, changing the myoelectric properties of the hyoid musculature. Performing strengthening exercises on an exercise ball and stretches in conjunction with naso-diaphragmatic breathing has been shown to improve posture.⁸⁶

Because decreased EMG activity and atrophy of the anterior neck muscles have been seen in a number of conditions including whiplash disorder and chronic neck pain, strengthening is appropriate. The patient should lie in the supine position while performing a forward nod of the head without excessive use of the sternocleidomastoid muscle (Figure 12-6). This exercise can be progressed to lifting the head while maintaining the nod and trying to hold that position for 5 to 10 seconds (Figure 12-6D). This exercise can also be performed in the seated position (Figure 12-7) during functional activities. Pain should be avoided with these exercises.¹³⁹⁻¹⁴²

Figure 12-6. Activation of the deep neck flexors. A, To monitor the activity of the sternocleidomastoid muscle, the patient can place their fingers on the muscle to monitor activity. B and C, In the supine position, the patient performs a small forward nod of the head without initial or excessive activity of the sternocleidomastoid muscle. D, Exercise may be progressed to a head lift while maintaining the head nod.

Figure 12-7. Activation of deep neck flexors in the seated position. A, Starting position. B, Ending position.

To improve the tone of the suprahyoid muscles, the tip of the tongue can be pressed to the center of the hard palate, holding it for 2 seconds. This can be repeated for 3 sets of 10 repetitions.¹⁴³

Chilling the skin of the neck, especially when the muscles are fatigued, often activates TrPs in anterior neck muscles. The patient should keep the neck warm, when possible, by sleeping in a high-necked sleep shirt, by wearing a turtleneck or scarf during the day, and by avoiding cold drafts.

Cutaneous I: Facial Muscles

Orbicularis Oculi, Zygomaticus Major, Platysma, Buccinator, Corrugator Supercilii and Procerus: “Wrinkle Wrecks”

Savas Koutsantonis

1. INTRODUCTION

The facial muscles lie in the subcutaneous tissue of the face. Most arise from the bones of the skull and insert into the skin. As flat, thin muscle sheets, they are distinct from other skeletal muscles in a morphologic aspect. The facial muscles serve as a sphincter or dilator of the facial orifices (orbit and mouth), and contraction of these muscles causes the skin of the face to move and wrinkle to form various emotional expressions. These movements are sensitive and do not demand significant force development. Facial muscles are not enveloped by definite fascia, and typical muscle bellies are never observed. The muscles vary considerably in their development among individuals, and there can be interlacing of fibers within adjacent facial muscles. They are innervated by different branches of the facial nerve. Pain patterns from facial muscle trigger points (TrPs) tend to be local. Activation and perpetuation of TrPs in these muscles frequently result from habitual facial expressions, dental appliances, or the playing of wind instruments. This group of muscles is also susceptible to the development of associated TrPs from active TrPs in larger muscle groups in the neck and the shoulder. Differential diagnosis of TrPs in these muscles includes blepharospasm. Corrective actions include self-stretching, treatment of active TrPs in the neck muscles that refer to the facial region, and breathing and relaxation exercises to decrease holding patterns within the face.

2. ANATOMIC CONSIDERATIONS

The facial muscles have distinct differences with regard to the fiber-type distribution and fiber size when compared with those of the limb muscles. The mean fiber diameter of the facial muscles (platysma, levator labii, zygomaticus major, and orbicularis oris) have been shown to be almost half that of normal limb muscles.¹

The fiber-type composition of the orofacial muscles has been found to be qualitatively

and quantitatively different from each other and from those of limb muscles. In general, the orofacial muscles contain a predominance of unusually high oxidative type II fibers. This composition is especially notable in the zygomatic minor, orbicularis oris, and orbicularis oculi muscles.^{2,3} Exceptions include the buccinator and occipitofrontalis muscles, which are composed primarily of type I fibers for maintaining longer duration facial tone.⁴

Orbicularis Oculi

The orbicularis oculi muscle is a broad, flat, elliptical muscle surrounding the circumference of the orbit that spreads into adjacent regions of the eyelids, anterior temporal region, infraorbital cheek and superciliary region⁵ (Figure 13-1). It is comprised of three parts (orbital, palpebral, and lacrimal) and a small ciliary bundle.⁵

Figure 13-1. Attachments of selected facial muscles and face-related cutaneous muscles. The orbicularis oculi, the zygomaticus major, and the platysma muscles are dark red. The palpebral portion of the orbicularis oculi muscle covers only the eyelids; the remaining fibers are the orbital portion. The zygomaticus major muscle reaches from the zygoma to the corner of the mouth. The platysma muscle connects the skin muscles near the mouth to the subcutaneous fascia of the upper chest. The orbicularis oris muscle is light red.

The orbital part arises from the medial palpebral ligament, frontal process of the

maxilla, and nasal component of the frontal bone. The fibers form complete ellipses, without interruption on the lateral side, with no bony attachment. The upper orbital fibers blend with fibers of the occipitofrontalis and corrugator supercilii muscles.

The palpebral part arises from the medial palpebral ligament and sweeps across the eyelids anterior to the orbital septum. The lacrimal portion arises from the upper part of the lacrimal crest, and the adjacent lateral surface, of the lacrimal bone. It passes laterally behind the nasolacrimal sac and divides into upper and lower slips. Some fibers are inserted into the tarsi of the eyelids close to the lacrimal canaliculi, but most continue across in front of the tarsi and interlace in the lateral palpebral raphe.⁵ Lastly, the ciliary bundle is comprised of a small group of fine fibers, behind the eyelashes.⁵

Buccinator

The buccinator muscle (Figure 13-2B), meaning trumpet player in Latin, is the principal muscle of the cheek, occupying the space between the maxilla and the mandible. The posterior part of the buccinator muscle is deep, internal to the mandibular ramus and in the plane of the medial pterygoid plate, attaching to the anterior margin of the pterygomandibular raphe. The anterior component converges toward the angle of the mouth where fibers intersect with the orbicularis oris muscle. The highest and lowest fibers continue forward to enter their corresponding sides of the lips. As the buccinator muscles course through the cheek on each side, a substantial number of fibers are diverted internally to attach to submucosa. The parotid duct pierces the buccinator opposite the third molar, where it lies on the deep surface of the muscle before opening into the mouth.⁵

Figure 13-2. Pain pattern and attachments of the buccinator muscle. A, Pain pattern (dark red) showing location of pain in the cheek and deep to it in the subzygomatic portion of the jaw. B, The buccinator muscle (medium red) blends anteromedially with the fibers of the orbicularis oris muscle (light red). Posterolaterally, it attaches chiefly to the tendinous inscription that also anchors the superior pharyngeal constrictor muscle (light red).

Zygomaticus Major

The zygomaticus major muscle occupies arises from the zygomatic bone, anterior to the zygomaticotemporal suture, and passes to the angle of the mouth, blending with fibers of levator anguli oris and orbicularis oris muscles^{5,6} (Figure 13-1).

Platysma

The platysma muscle is a broad sheet of a muscle arising from the superficial pectoral and deltoid fascia; passing over the clavicle; and inserting into the inferior body of the mandible, skin and tissue of the lateral half of the lower lip^{5,6} (Figure 13-1). Although the platysma muscle is described as a neck muscle, it is considered a contributor to the orbicularis oris complex since it has mandibular, labial, and modiolar portions, which are called the pars mandibularis, pars labialis, and pars modiolaris, respectively. The pars mandibularis attaches to the lower border of the body of the mandible; the pars labialis attaches to the tissue of the lateral half of the lower lip, as a direct labial retractor; while the pars modiolaris comprises all of the remaining bundles posterior to the pars labialis and attaches to the modiolus as one of the modiolar muscles.^{5,7} In one study^{5,7} 40.5% of cadaver specimens showed blending of the lateral deep slip of the platysma muscle into the inferior part of the buccinator muscle. Due to broad insertions of the platysma into the lower face, its connections with surrounding structures are important with respect to the formation of facial expressions.^{5,7}

Corrugator Supercilii

The corrugator supercilii muscle is a small pyramidal muscle located at the medial end of each eyebrow, lying deep to the occipitofrontalis and orbicularis oculi muscles, with which it interdigitates. It arises from bone at the medial end of the superciliary arch and its fibers pass laterally and upward to exert traction on the skin above the middle of the supraorbital margin.⁵

Procerus

The procerus muscle arises from the fascia attached to the periosteum covering the lower part of the nasal bone and the upper parts of the lateral nasal cartilages. It inserts into the skin on the forehead between the eyebrows, interdigitating with the frontalis muscles on each side.⁵

2.1. Innervation and Vascularization

Orbicularis Oculi

Innervation is supplied by temporal and zygomatic branches of the facial nerve. Vascular supply is provided by branches of the facial, superficial temporal, maxillary, and ophthalmic arteries.⁵

Zygomaticus Major

Innervation is supplied by the zygomatic and buccal branches of the facial nerve. Vascular supply is provided by superior labial branch of the facial artery.⁵

Platysma

Innervation is supplied by the cervical branch of the facial nerve. Vascular supply is provided by the submental branch of the facial artery and by the suprascapular artery (from the thyrocervical trunk of the subclavian artery).⁵

Buccinator

Innervation is supplied by the buccal branch of the facial nerve. Vascular supply is provided by branches from the facial artery and the buccal branch of the maxillary artery.⁵

Corrugator Supercilii

Innervation is supplied by the temporal branches of the facial nerve. Vascular supply is provided by branches from adjacent arteries, mainly from the superficial temporal and ophthalmic arteries.⁵

Procerus

Innervation is supplied by the temporal and lower zygomatic branches of the facial nerve; a supply from buccal branches has also been described. Vascular supply provided by branches from the facial artery.⁵

2.2. Function

Facial muscles are unique in that they do not cross joints and they function to either open and close the apertures of the face or to tug skin into intricate movements that produce facial expressions.⁸

Orbicularis Oculi

The orbicularis oculi muscle is the sphincter muscle of the eyelids and plays important roles

in both facial expression and protective blink reflexes.⁵

The orbital portion of the muscle produces vertical furrowing, narrowing of the palpebral fissure, and bunching or protrusion of the eyebrows.⁵ This more forceful eyelid closure of the orbital portion can compress the lacrimal sac to produce tears into the nasolacrimal duct.⁶ The palpebral portion performs light closure of the eyelids usually with sleep, or reflexively, as in blinking in a protective manner. When the entire orbicularis oculi muscle contracts, it causes folds that radiate from the lateral angle of the eye. With hyperactivity, this muscle causes wrinkles called “crow’s feet.”⁵ Reduced or absent orbicularis oculi function (from palsies, trauma, or surgery) results in the inability to completely close the eyelid or to blink, exposing the cornea to break down, scarring, dry eye, and possible vision loss.⁹

Buccinator

Movement of food about the mouth depends on interplay between the tongue and the buccinator muscles. Contraction of the buccinator muscles compresses the cheek against the teeth and gums to decrease the size of the oral cavity.⁵ When the cheeks have been distended with air, the buccinator muscles expel the air between the lips, as in whistling or playing a wind instrument. Cadaver studies have demonstrated that distinct muscle fibers from the buccinator muscle extend to and insert into the terminal portion of the carotid duct, giving it a physiologic role in salivary secretion.¹⁰

Zygomaticus Major

This muscle draws the angle of the mouth upward and laterally, as in smiling and laughing.⁵

Platysma

Contraction of the platysma muscle reduces the concavity between the jaw and the side of the neck, producing tense oblique ridges in the skin of the neck. It can also assist in depressing the mandible, by drawing down the lower lip and corners of the mouth, as with expressions of horror or surprise.⁵ As confirmed by electromyography, the muscle is also active with large vertical jaw opening movements, but not during swallowing or neck movements.¹¹ Contraction of the lateral deep slip of the platysma muscle provides tension to the inferior part of the buccinator muscle, pulling it inferolaterally. In addition, the fibers of the slip that course longitudinally with the inferior fibers of the buccinator muscle may be involved in retraction of the lower lip, along with the buccinator muscles.⁷

Corrugator Supercilii

This muscle, in cooperation with the orbicularis oculi muscle, draws the eyebrow downward and medially to shield the eyes in bright light. It is also involved in frowning or

deep concentration. The combined muscle action produces mainly vertical wrinkles on the supranasal strip of the forehead.⁵

Procerus

The procerus muscle draws down the medial angle of the eyebrows, producing transverse wrinkles over the bridge of the nose. As with the corrugator supercilii muscle, it is active during frowning and concentration and can help shield the eyes in bright sunlight.⁵

2.3. Functional Unit

Closure of the upper lid by the orbicularis oculi muscle is antagonized by the levator palpebrae muscle. The orbital portion of this muscle works synergistically with the corrugator supercilii and procerus muscles to create furrowing of the eyebrows.

The tongue works with the buccinator muscles to control the food during chewing. The muscles of exhalation work in close cooperation with the buccinator muscles when one is blowing a wind instrument. The orbicularis oris muscle frequently works in concert with the buccinator muscles for movements of the lips. The zygomaticus major muscle is assisted by the parallel-running fibers of the zygomaticus minor muscle, which also is known as the zygomatic head of the quadratus labii superioris muscle.¹²

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Orbicularis Oculi

This is one of the few muscles from which TrPs refer pain to the nose (Figure 13-3A). Currently, no other muscle is known to refer pain to the tip of the nose. Less intense pain may be felt in the cheek, close to the nose, and over the upper lip ipsilaterally.¹³

Figure 13-3. Pain patterns (dark red) and muscle (light red). A, Orbital portion of the right orbicularis oculi muscle. B, Right zygomaticus major muscle. C, Right platysma muscle.

Zygomaticus Major

Trigger points in this muscle refer pain in an arc that extends along the side of the nose and then upward over the bridge of the nose to the mid-forehead (Figure 13-3B).¹³

Platysma

Trigger points in the platysma muscle usually overlie the sternocleidomastoid muscle and refer a prickling pain to the skin over the lateral surface of, and just below, the ipsilateral mandible (Figure 13-3C). A platysma TrP just above the clavicle may refer hot prickling pain across the front of the chest.

Buccinator

With TrPs in the buccinator muscle, the patient experiences pain locally in the cheek (Figure 13-2A) and pain referred deep to the cheek as a subzygomatic ache in the jaw.¹⁴

Corrugator Supercilii

Trigger points in this muscle project pain over the forehead and deep into the head, contributing to frontal headaches.

Procerus

As with the corrugator supercilii muscle, referred pain is projected over the forehead and deep into the head.

3.2. Symptoms

Individuals with myofascial dysfunction of the orbicularis oculi muscle may complain of “jumpy print” when reading. Eye strain and pain can be reported with visually demanding computer work.¹⁵

Patients with platysma TrPs will report a prickling pain that feels like multiple pinpricks in the area of referral. The sensation is not like the tingling caused by an electric current, a feature that usually denotes a neurologic origin.

Frontal headaches can be induced from corrugator supercilii and procerus TrPs and can mimic or combine with the TrP referral patterns of the sternocleidomastoid muscle.

When the buccinator muscle is involved, chewing may aggravate subzygomatic jaw pain. The patient may have a perception of difficulty in swallowing, although the swallowing movement appears normal.¹⁴

3.3. Patient Examination

After a thorough, subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. A detailed medical history and screen of the cranial nerves are also essential to establish a proper diagnosis and plan of care. Activation of TrPs in the orbicularis oculi muscle may produce a unilateral narrowing of the palpebral fissure that resembles the ptosis of Horner's syndrome but without the change in pupillary size. When upward gaze is tested, these patients tilt the head backward because they cannot raise the upper eyelid sufficiently to look up.

Involvement of the zygomaticus major muscle may cause restriction of normal jaw opening by 10 or 20 mm; as a result this muscle should be assessed along with the masseter and temporalis muscles and the temporomandibular joint (TMJ) for restriction of mandibular opening. Patients presenting with frontal headaches are often found with TrPs in temporal, suboccipital and shoulder musculature,^{16,17} therefore, a thorough examination of these regions should be included along with local facial muscles.

3.4. Trigger Point Examination

Currently there are no reliability studies on the identification of TrPs in the cutaneous facial muscles.

Orbicularis Oculi

The TrPs in the upper orbital portion of this muscle are found by using a cross-fiber flat palpation to the muscle fibers that lie above the eyelid, just beneath the eyebrow and against the bone of the orbit. The lower portion can be palpated by rolling the muscle fibers and skin between the fingers to localize the TrP.

Buccinator

Trigger points in this muscle are commonly found mid-cheek, halfway between the angle of the mouth and the ramus of the mandible. The clinician uses a cross-fiber pincer palpation with one finger on the inside of the cheek and one finger outside. The band can be identified by sliding the inside finger up and down against the counterpressure of the outside finger, while squeezing gently. Tenderness of the TrP can be further increased by pulling the cheek outward, since this places the buccinator muscle on increased tension. Pulling and snapping the TrP in the taut band produces a painful, palpable, and usually visible local twitch response in this superficial muscle. See Figure 13-4 for a similar technique.

Figure 13-4. Palpation of the left zygomaticus major muscle, using pincer grasp to localize the TrPs between the digits.

Zygomaticus Major

To examine the zygomaticus major muscle, the patient relaxes, either sitting or preferably supine, with the mouth open. Most of the length of the muscle can be palpated for spot tenderness by using a cross-fiber pincer palpation, with one finger inside the cheek and the other on the outside of the cheek, while pulling the muscle laterally taking up tissue slack (Figure 13-4). The palpable taut band is felt chiefly by the outside finger. External flat cross-fiber palpation may also be used for examination. Trigger points are commonly found in this muscle closer to the attachment of the muscle in the orbicularis oris muscle.

Platysma

Trigger points in the platysma muscle are assessed with the patient in sitting, or supine, tipping the head back far enough to take up the slack of the muscle. The clinician utilizes pincer palpation approximately 2 cm (1 in) above the clavicle to locate TrPs throughout the muscle (Figure 13-5). Patients will commonly complain of a prickling sensation in the face with pincer palpation of the platysma (Figure 13-3).

Figure 13-5. Examination of the platysma utilizing pincer palpation.

Corrugator Supercilii

Trigger points in the corrugator supercilii muscle are assessed by cross-fiber flat (Figure 13-6A) or pincer palpation (Figure 13-6B) with the patient in sitting or supine.

Figure 13-6. Examination of the corrugator supercilii muscle. A, Cross-fiber flat palpation. B, Pincer palpation.

Procerus

As with the corrugator supercilii muscle, this muscle is assessed by using a cross-fiber flat (Figure 13-7A) or pincer palpation (Figure 13-7B) to identify taut bands and TrPs with the patient in sitting or supine.

Figure 13-7. Examination of the procerus muscle. A, Cross-fiber flat palpation. B, Pincer palpation.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of any of the facial muscles, TrPs may be activated by maximal or submaximal concentric loading,¹⁸ as with habitual facial expressions. Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. Habitual frowning, squinting (due to photophobia or astigmatism), visual straining from computer work or TrPs in the sternal division of the sternocleidomastoid muscle (which refer pain to the orbit) may activate TrPs in the orbicularis oculi, corrugator supercilii and procerus muscles.¹³ It is important to

differentiate referred pain patterns of head, neck, and shoulder muscles in patients presenting with headache symptoms. Myofascial dysfunction of the masticatory muscles that is severe enough to cause trismus may activate TrPs in the zygomaticus major muscle. Stressful clenching of the jaw and even static bracing of orofacial muscles can lead to the development of facial muscle TrPs.

Platysma TrPs are typically associated with TrPs in the sternocleidomastoid and scalene muscles.

Buccinator TrPs may be activated by poorly fitted dental appliances or from the repetitive activation of muscles when playing wind instruments.

4.2. Associated Trigger Points

It has been shown that associated TrPs can develop in the referred pain areas of primary active TrPs,¹⁹ therefore muscles that can refer to the facial region should be considered. Muscles such as the sternocleidomastoid, upper trapezius, masseter, temporalis and lateral pterygoid muscles can refer to different areas of the face, contributing to associated TrPs in the facial muscles. These associated TrPs will not improve with treatment until TrPs in the primary muscles are treated effectively.

Pain caused by TrPs in the orbicularis oculi, buccinator, and/or zygomaticus muscles is easily attributed erroneously to a form of tension headache. Patients with pain from buccinator TrPs are very likely to receive a misdiagnosis of TMJ dysfunction, especially since they have trouble chewing and swallowing, therefore TMJ dysfunction should be ruled out.

The sternocleidomastoid, scalene and masticatory muscles on the same side often contain active TrPs, and can produce associated TrPs in the platysma muscle which overlies this area.

4.3. Associated Pathology

Blepharospasm is a focal (usually bilateral) dystonia of the orbicularis oculi muscles causing abnormal eyelid closure, blinking, or twitching which can cause significant irritation. This condition is neurologically based, therefore it should not be confused with TrPs in this muscle. Botulinum toxin injection is used effectively in managing these symptoms.²⁰

Tightness and TrPs in the corrugator supercilii muscle can result in nerve entrapment or pressure on the supratrochlear nerve causing frontal headache symptoms.²¹ Compression or impingement of any branch of the trigeminal nerve (V1-ophthalmic, V2-maxillary, V3-mandibular) can mimic a frontal headache or orbital and facial pain patterns and should be considered.²²

5. CORRECTIVE ACTIONS

The patient should be taught to palpate these facial muscles to locate taut bands and tender points and to appropriately apply sustained digital pressure to inactivate the identified

TrPs.

Self-stretching of the zygomaticus major (Figure 13-8A) and buccinator (Figure 13-8B) muscles can be performed with one finger in the mouth and one finger outside the mouth, holding and pulling the taut tissue outward.

Figure 13-8. A, Self-stretching of the zygomaticus major muscle. B, Self-stretching of the buccinator muscle.

Any TrPs in other muscles that are likely to refer pain to the same side of the face, such as the upper trapezius, sternocleidomastoid, and masticatory muscles, should be treated. Refer to Chapters 6, 7, 8, 9, and 11 for specific corrective actions for each of these muscles.

The patient should avoid excessive facial straining, this is especially important for those who work extensively at a desk and use a computer. Proper ergonomics and postures, along with wearing appropriate corrective lenses when needed to reduce visual strain, squinting, and facial stress can help to reduce this strain.

Hyperactivity of facial expression, holding patterns related to anxiety, tension, and visual stress (as with computer use) can lead to facial TrPs. A program of breathing, relaxation exercises, and self-awareness of habitual patterns can be helpful to minimize overuse of these muscles.

Cutaneous II: Occipitofrontalis

“Head Tightness Twins”

Savas Koutsantonis and Jennifer L. Freeman

1. INTRODUCTION

The epicranium or occipitofrontalis muscle is generally regarded as one muscle composed of two distinct muscle bellies. It has a broad, musculofibrous layer that covers the vertex of the skull. The frontalis muscle adheres to the superficial fascia of the eyebrows and has no bony attachment. The occipitalis muscle originates at the mastoid process of the temporal bone and the lateral two-thirds of the superior nuchal line of the occipital bone. The muscle bellies of the frontalis and occipitalis are joined through the galea aponeurotica (epicranial aponeurosis), which covers the vertex of the skull. The temporal branch of the facial nerve innervates the frontalis muscle, and the posterior auricular branch innervates the occipitalis. Both muscle bellies work together for facial expressions. Frontalis trigger points (TrPs) refer pain on the ipsilateral forehead, whereas occipitalis TrPs refer diffusely over the back of the head and through the cranium, causing intense pain deep in the orbit. Trigger points in either muscle belly can be perpetuated by prolonged facial expressions or from TrPs in cervical muscles that refer to the head. Associated pathology may include nerve entrapment, tension-type headache (TTH), and migraine headache. Corrective actions include eliminating TrPs in cervical muscles and addressing factors that can contribute to excessive or prolonged facial expressions.

2. ANATOMIC CONSIDERATIONS

The occipitofrontalis muscle covers the dome of the skull from the eyebrows anteriorly, to the highest nuchal lines posteriorly. The frontal belly intertwines with the corrugator supercilii, procerus, and orbicularis oculi muscles, which act together to provide variations of facial expression. The occipital belly is, asymmetrical on both sides. The shape of this muscle varies greatly; cadaver studies show that irregular shapes are most common, followed by quadrangular, and then ellipse shapes. The occipital muscle bellies are often

illustrated with muscle fibers angled in a straight line toward the frontal bellies with both sides close to each other. More recent studies not only suggest variations in shape but also fiber direction ranging in angles from 55° to 65° from the horizontal plane and variation in distance between the bellies.¹⁻³

The muscle bellies of the frontalis and occipitalis are joined through the galea aponeurotica (epicranial aponeurosis),² which covers the vertex of the skull (Figure 14-1). Although the galea aponeurotica is firmly connected to the skin, it does slide over the periosteum⁴ which allows both portions of the muscle to function with each other. The frontalis muscle adheres to the superficial fascia of the eyebrows and has no bony attachment.⁴ Its fibers blend with those of the adjacent muscles; including the procerus, corrugator supercilii, and orbicularis oculi muscles; and ascend to join the epicranial aponeurosis.^{4,5} The occipitalis muscle originates at the mastoid process of the temporal bone and the lateral two thirds of the superior nuchal line of the occipital bone. The superficial fascia overlying the occipital belly becomes the temporoparietal fascia and ends at the superior end of the frontal belly, creating a superficial musculoaponeurotic system. Underneath this superficial system, the occipital belly becomes the galea aponeurotica and enters into the underside of the frontal belly, creating a deep musculoaponeurotic system which pulls on the superficial system with activation.^{1,2,4,5}

Figure 14-1. Attachments of the left epicranial muscles (*dark red*); the *frontalis* and *occipitalis* bellies of the occipitofrontalis muscle, and also the *temporoparietalis* muscle. Each connects above to the tendinous galea aponeurotica. Below and anteriorly, the frontalis muscle attaches to the skin near the eyebrow; the occipitalis muscle attaches to the bone along the superior nuchal line, and the temporoparietalis muscle to the skin above the ear. The cutaneous *orbicularis oculi* muscle is shown in light red.

2.1. Innervation and Vascularization

The occipitofrontalis muscle is supplied by the facial nerve (cranial nerve VII), with the temporal branch innervating the frontalis and the posterior auricular branch innervating the occipitalis.⁵ The posterior auricular nerve is the first extracranial branch of the facial nerve and although it is a delicate structure, it has clinical significance. This branch serves as a landmark when identifying the main trunk of the facial nerve. It is useful to surgeons to minimize damage to the facial nerve during surgeries such as a parotidectomy and

mastoidectomy. This nerve also contributes cutaneous sensation from the skin over the mastoid process and parts of the auricle. It is most typically found as a single branch coming off the main trunk of the facial nerve, but it can also divide into two or three branches. These additional branches dive into the parotid gland.^{1,6}

The vascular supply to the frontalis muscle is through the frontal branch of the superficial temporal and the ophthalmic arteries. The occipitalis is supplied by the posterior auricular and occipital arteries.⁴

2.2. Function

The frontalis muscle is voluntarily contracted when facial expressions are made. When acting from above, it raises the eyebrow and skin over the root of the nose as in expressions of surprise or horror.⁷ Acting from below, it draws the scalp forward creating transverse wrinkles on the forehead.^{4,5} It works with the corrugator supercilii and orbicularis oculi muscles during eye opening and closing (performed either smoothly or maximally) and with a straight gaze and frowning.⁸ As several studies have shown, the frontalis muscle is also associated with increased muscle tension during stress or anxiety, as well as in individuals with TTH because electromyographic (EMG) activity is higher and pressure pain threshold (PPT) is lower when compared with control groups.^{9–11}

The occipitalis muscle becomes the galea aponeurotica and enters into the underside of the frontalis muscle becoming the deep musculoaponeurotic system anchored to the occipital bone. When activated, it draws the superficial musculoaponeurotic system backward with the scalp. When only the frontalis muscle contracts to lift the eyebrow and upper eyelid, it draws the scalp forward which results in wrinkling and narrowing of the forehead. When both the frontalis and occipitalis muscles contract to maximize the eyebrow and upper eyelid lifting, the galea aponeurotica draws the superficial musculoaponeurotic system backward with the frontalis muscle, resulting in a less-wrinkled forehead despite the contraction of the frontalis muscle.^{2,4} Acting alternately, the frontalis and occipitalis muscles can move the entire scalp backward and forward.

The frontalis and occipitalis muscle bellies can also work together to lift the eyebrows to maintain a clear visual field. An upward gaze position up to 30° increases frontalis activity only, whereas a greater than 40° involves contraction of both the frontalis and occipitalis parts. Occipitalis EMG values increase significantly as the degree of gaze becomes higher.²

2.3. Functional Unit

The frontalis and occipitalis muscles function as synergists in tandem. The frontalis muscle may contract with, or independently of, the perpendicularly placed corrugator muscle which shortens the eyebrows in a frown.

The frontalis muscle works synergistically in a dynamic balance with the corrugator supercilii and the orbicularis oculi muscles during eye opening and closing as well as with straight gazing and frowning.⁸ The frontalis muscle is an antagonist to the procerus muscle

which pulls the medial end of the eyebrow down.¹²

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Frontalis

Trigger points in the frontalis muscle evoke pain that spreads upward and over the forehead on the same side (Figure 14-2A). The referred pain commonly remains local in the region of the muscle.¹³

Figure 14-2. Pain patterns (*dark red*) referred from TrPs in the occipitofrontalis muscle (*medium red*). A, Right frontalis muscle belly. B, Left occipitalis muscle belly.

Occipitalis

Trigger points in the occipitalis muscle are a recognized source of headache.¹⁴ These TrPs often form secondarily to TrPs in the suboccipital muscles, which can refer pain over the occipital and temporal bones.¹⁵ Commonly, TrPs in the occipitalis muscle refer pain laterally and anteriorly, diffusely over the back of the head and through the cranium,

causing intense pain deep in the orbit (Figure 14-2B). This muscle also produced an “earache” sensation when injected with hypertonic saline.¹⁶ Cyriax⁷ found that injections into the galea aponeurotica referred pain ipsilaterally behind the eye, in the eyeball, and in the eyelids. These referred pain patterns were later confirmed clinically by Williams.¹⁷

3.2. Symptoms

Patients with occipitalis TrPs typically report having to sleep on their side at night due to the inability to tolerate the back of the head on the pillow because of the pressure of the head compressing TrPs.

The deep-aching occipital pain caused by occipitalis TrPs should be distinguished from symptoms associated with the entrapment of the greater occipital nerve by the posterior cervical muscles; including the upper trapezius, oblique capitis inferior, and semispinalis capitis muscles;^{18–20} and from referred pain by the head, neck, and shoulder musculature such as upper trapezius, sternocleidomastoid, splenius capitis, temporalis, masseter, levator scapulae, and superior oblique and suboccipital muscles.^{9,21}

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Additionally, patients presenting with frontal or occipital pain require more than a local examination. Several studies have demonstrated that the referred pain elicited by TrPs from neck, shoulder, and head muscles reproduces the headache pattern in patients with TTH, migraine, and cervicogenic headaches.^{9,17,21,22} Therefore, a thorough examination is required of the suboccipital, the cervical, and the shoulder muscles to identify TrPs that can elicit familiar pain patterns.

Cervical zygapophyseal joints also need to be considered as a source for referred pain to the occipital region. Subjects who underwent cervical zygapophyseal injection and radiofrequency facet denervation reported occipital symptoms when performed at C0-C1 to C3-C4, with the highest percentage of reported occipital symptoms from C2 to C3. As a result, cervical facet joint disorders and accessory motion restrictions should be addressed as a possible source of occipital headaches.²³

Sensitization from possible compression or entrapment of the ophthalmic branch (V1) of trigeminal cranial nerve (V) should also be considered. The sensory distribution of this nerve mimics the frontal headache (HA) symptoms.²⁴

3.4. Trigger Point Examination

A TrP in the frontalis muscle is identified with cross-fiber flat palpation, commonly above the eyebrow, within the muscle fibers (Figure 14-2A). A very gentle pressure is necessary to ensure the clinician does not press through the TrP and miss it. A TrP in this muscle can

feel like a small grain of rice.

A TrP in the occipitalis muscle is often found in the small hollow just above the superior nuchal line. A cross-fiber flat palpation is used to identify the TrP. Difficulty in properly localizing this muscle lies in the great variability in shape, size, and location; therefore, repeated contraction by elevation of the eyebrows with upward gaze may be necessary to isolate the proper location of this muscle.¹

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the occipitofrontalis muscle, TrPs may be activated by maximal or submaximal concentric loading,²⁵ which for this muscle is frequently due to habitual facial expressions.²¹

The frontalis muscle may be activated by work overload, especially in anxious or tense people with great mobility of facial expression, and in people who persistently use the frontalis in an expression of attention with raised eyebrows and a wrinkled forehead. Excessive or prolonged gazing, along with maintained depressed eyebrows or frowning, also overactivates the frontalis muscle.⁸

Occipitalis TrPs are likely to occur in patients with decreased visual acuity due to persistent, strong contraction of the forehead and scalp muscles. Sustained eyebrow elevation in an effort to maintain an upward gaze significantly increases the activation of this muscle.²

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.²⁵ Therefore, musculature in the referred pain areas for each muscle should also be considered.²⁶ Because active TrPs in the frontalis muscle are often associated TrPs from long-standing TrPs in the clavicular division of the sternocleidomastoid muscle on the same side, this muscle should be examined. Lasting relief may also depend on inactivating associated TrPs in suboccipital, upper trapezius, sternocleidomastoid, and temporalis muscles that can refer symptoms to the frontal region of the head. Trigger points in the occipitalis can result from TrPs in the upper trapezius, sternal division of the sternocleidomastoid, and posterior cervical muscles, which refer pain and tenderness to the occipital region.²¹ Additionally, the posterior digastric and levator scapulae muscles can refer to this region and contribute to associated TrPs of the occipitalis muscle.

4.3. Associated Pathology

Pain caused by TrPs in these muscles is likely to be diagnosed as TTH without any recognition of the treatable source. Mixed mechanisms such as neurovascular, neuropathic, myofascial, and cervicogenic may all contribute and should therefore be examined as

possible contributing factors.²⁷ Peripheral nerve compression or entrapment should be considered when assessing for occipital or supraorbital neuralgias. The greater occipital nerve can be compressed as it courses through the inferior capitis oblique muscle, semispinalis capitis muscle, and cranial insertions of the upper trapezius muscle.^{19,20} The supraorbital nerve can be entrapped by the facial muscles including the frontalis muscle.²⁸ This mechanical pressure on the peripheral nerve can be relieved by inactivating the TrP.

In cases of atypical history of pain, with no other signs and symptoms other than occipital headaches, further interdisciplinary referral and imaging may be necessary to exclude neurovascular pathology. One such case was reported of an internal carotid artery aneurysm presenting as orofacial pain and occipital headache.²⁹

5. CORRECTIVE ACTIONS

When TrPs are found in the occipitofrontalis muscle, the patient should avoid persistent frowning and vigorous wrinkling of the forehead because this can continue to aggravate and/or perpetuate the development of TrPs.

Any associated TrPs in the clavicular division of the sternocleidomastoid and posterior neck muscles should be inactivated. Addressing perpetuating factors to the development of TrPs in the sternocleidomastoid and posterior neck muscles should also be done. (See Chapters 7, 15, and 16.) Correction of forward head posture is also necessary to reduce the strain on the sternocleidomastoid, splenii, and posterior cervical muscles that may have TrPs.

The frontalis muscle responds well to self-pressure release of TrPs (Figure 14-3). The same may be used for TrPs in the occipitalis muscle, with the patient using digital pressure to release the TrPs (Figure 14-4).

Figure 14-3. Self-pressure release of frontalis TrPs. In a sitting or standing position, the

patient gently presses on the TrP in the muscle that is contributing to his or her pain.

Figure 14-4. Self-pressure release of occipitalis TrPs. In a sitting or standing position, the patient gently presses on the TrP in the muscle that is contributing to his or her pain.

A program of self-awareness, breathing, and relaxation exercises may be helpful for patients with frontalis TrPs because decreased cognitive stress has been shown to increase resting activity of this muscle.¹¹

Splenius Capitis and Splenius Cervicis Muscles

“Corner of the Neck and Crown Complaints”

César Fernández de las Peñas, Jaime Salom-Moreno, and Michelle Finnegan

1. INTRODUCTION

The splenius capitis and cervicis muscles are the main posterior stabilizers of the cervical spine. The splenius capitis muscle originates from the mastoid process and occipital bone, just below the superior nuchal line. It inserts onto the spinous processes of the seventh cervical and upper three to four thoracic vertebrae and the supraspinous ligament. The splenius cervicis muscle originates from the transverse process of the atlas (C1) and axis (C2) as well as the posterior tubercle of the third cervical vertebra (C3). It inserts onto the third through sixth thoracic spinous processes (T3-T6). The splenius capitis muscle is innervated by the lateral branches of the second and third cervical dorsal rami (C2-C3), whereas the splenius cervicis muscle is innervated by the lateral branches of the lower cervical dorsal rami (C4-C6). Both muscles contribute to the dynamic stability of the neck by controlling movement during cervical extension. Furthermore, these muscles protect the neck during cervical flexion movements such as those during a whiplash injury. Their main function, when acting bilaterally, is extension of the cervical spine, whereas when they act unilaterally, they rotate the neck. Referred pain from splenius capitis trigger points (TrPs) can spread to the vertex of the head; splenius cervicis TrPs refer pain behind the eye and sometimes to the occiput. Activation and perpetuation of TrPs in these muscles include whiplash, poor posture when sitting at a desk, using a handheld electronic device, or playing musical instruments. Environmental or activity-based stresses can also play a role. These muscles can be implicated in different pain syndromes of the cervical spine, particularly mechanical neck pain and whiplash. In addition, TrPs in these muscles have been associated with individuals with cervical radicular pain or fibromyalgia syndrome. The main corrective actions include postural correction and education in ergonomics at work and home.

2. ANATOMIC CONSIDERATIONS

Splenius Capitis

The splenius capitis muscle originates from the mastoid process, underneath the attachment of the sternocleidomastoid muscle, and the rough surface on the occipital bone just below the lateral third of the superior nuchal line. It inserts onto the tips of the spinous processes of the seventh cervical vertebra, the upper three or four thoracic vertebrae, and the intervening supraspinous ligaments (Figure 15-1).¹ The tendons of the upper fibers of the splenius capitis muscle interlace at the midline with those of the contralateral splenius capitis muscle and with the upper trapezius and rhomboid minor muscles. This convergence point forms the dorsal raphe of the ligamentum nuchae in the lower half of the cervical region.²

Figure 15-1. Attachments of the right splenius capitis muscle (upper dark red) and of the right splenius cervicis muscle (lower dark red). Adjacent muscles are shown in light red. The levator scapula muscle (right side, cut) crosses over the upper part of the splenius cervicis muscle, with which it has common attachments to the transverse processes of the upper cervical vertebrae. The trapezius muscle (not shown) covers much of both the splenii muscles.

Splenius Cervicis

The splenius cervicis muscle lies to the lateral side and caudal to the splenius capitis muscle. This muscle originates from the transverse process of the atlas (C1), the tip of the transverse process of the axis (C2), and the posterior tubercle of the third cervical vertebra (C3). It inserts onto the third through sixth thoracic spinous processes (T3-T6) (Figure 15-1).¹ On the cranial attachment of the muscle, the splenius cervicis muscle forms the most posterior of a triple attachment with the levator scapulae muscle in the middle and the scalenus medius muscle in front. Bilaterally, each of the paired splenius cervicis and splenius capitis muscles form a “V” shape.

2.1. Innervation and Vascularization

The splenius capitis muscle is innervated by the lateral branches of the second and third cervical dorsal rami (C2-C3), whereas the splenius cervicis muscle is innervated by the lateral branches of the lower cervical dorsal rami (C4-C6).¹ The dorsal muscles of the cervical spine receive their blood supply from the vertebral artery, deep cervical artery, superficial and deep descending branches of the occipital artery, and deep branch of the transverse cervical artery, when present.¹

2.2. Function

Splenius Capitis

The splenius capitis muscle is active bilaterally during extension of the head and neck³⁻⁵ and unilaterally during rotation of the face to the same side.³ Takebe et al⁶ has shown that the splenius capitis muscle demonstrates no activity at rest in the upright balanced position, and it does not become active during lateral flexion of the head and neck. Other authors have shown that the muscle is active, at least somewhat, during lateral flexion.^{4,7,8} When the face is rotated to one side with the chin tilted upward, the splenius capitis muscles on *both* sides work vigorously. When in this rotated and extended position, the muscle on the same side rotates the head and neck; the opposite muscle helps extend the head and the neck.⁶ The splenius capitis muscle also plays a subordinate role in ipsilateral tilting of the head.⁹ More recent studies have observed that the activity of the splenius capitis muscle is not consistent during voluntary cervical motions depending on the initial position of the head.¹⁰ This muscle is also active during cervical flexion,¹¹ most likely to assist in controlling the forward motion of the head.

Splenius Cervicis

Despite a lack of supportive electromyographic evidence, it is assumed that the splenius cervicis muscle rotates the upper cervical vertebrae when acting unilaterally and extends the cervical spine when acting bilaterally. Its role during lateral flexion of the cervical spine is

also questionable. However, it has been demonstrated that this muscle is active during cervical flexion,¹¹ most likely to assist in controlling the forward motion of the head and the neck.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 15.1 grossly represents the functional unit of the splenii muscles.¹²

Box 15-1 Functional unit of the splenius capitis and cervicis muscles

Action	Synergists	Antagonist

Head rotation	Ipsilateral levator scapulae Contralateral upper trapezius Contralateral semispinalis cervicis Contralateral deep spinal rotator muscles Contralateral sternocleidomastoid	Contralateral levator scapulae Ipsilateral upper trapezius Ipsilateral semispinalis cervicis Ipsilateral deep spinal rotator muscles Ipsilateral sternocleidomastoid

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the splenius capitis muscle usually refer pain to the vertex of the head on the same side (Figure 15-2A).¹³ Schmidt-Hansen et al¹⁴ observed that a hypertonic saline injection into the splenius capitis muscle induced referred pain to the trigeminal innervated dermatomes, particularly the ophthalmic area of the head (vertex).

Figure 15-2. Referred pain patterns (dark red) for the right splenius capitis and splenius cervicis muscles (medium red). A, Referred pain from TrPs located in the upper portion of the splenius capitis, the only section of the muscle directly palpated. B, Trigger points in the splenius *cervicis* muscle refer pain to the orbit (pain figure on the left). The black dash line and arrow indicate that the pain seems to shoot through the inside of the head to the back of the eye. Splenius cervicis TrPs can also refer pain to the angle of the neck (figure on the right).

Trigger points in the upper portion of the splenius cervicis (Figure 15-2B, pattern on far left of the figure) usually refer diffuse pain through the inside of the head that focuses

strongly behind the eye on the same side and sometimes to the ipsilateral occiput. Trigger points in the lower portion of the splenius cervicis, at the angle of the neck (Figure 15-2B, middle figure) refer pain upward and to the base of the neck (Figure 15-2B, pattern on far right of the figure). This pattern generally lies within the upper part of the pain pattern of the levator scapula, but it can include pain spread more medially.

In addition to pain, a TrP in the upper portion of the splenius cervicis muscle may cause blurring of the vision in the ipsilateral eye without dizziness or conjunctivitis.

The referred pain patterns of TrPs in these muscles have mistakenly been diagnosed as occipital neuralgia in three patients as reported in Graff-Radford et al.¹⁵ Prior to the diagnosis of myofascial pain, other treatments did not provide successful relief of symptoms. Once the correct diagnosis was made, two of the three patients were successfully treated. The third patient was not successfully treated due to inability to follow-up with care; however, the initial release of TrPs in the splenii capitis and cervicis muscles fully eliminated the pain for 2 days.

3.2. Symptoms

Patients with active splenius capitis TrPs usually present with a primary complaint of pain referred close to the vertex of the head, as described earlier in this chapter.

Patients with splenius cervicis TrPs primarily report pain in the neck, cranium, and eye; they may also report a “stiff neck,”¹⁶ because active rotation of the head and neck is limited by pain.

Pain in the orbit and blurring of vision are disturbing symptoms that are occasionally referred unilaterally to the eye from TrPs in the upper part of the splenius cervicis muscle.

Patients with TrPs in the splenii capitis and cervicis muscles may also report a pressure-like pain in the occipital region, a pressure-like pain that radiates to the forehead, and/or numbness in the occipital region.¹⁵

3.3. Patient Examination

Observation of posture typically reveals a forward head position with an extended upper cervical spine and a flexed lower cervical spine. A lateral tilt of the head may also be observed. The patient oftentimes demonstrates painful and limited active cervical rotation to the same side and passive cervical rotation limited to the opposite side. Active cervical flexion may be limited by one or two finger widths.

Joint accessory motion testing of the upper cervical (C0-C1; C1-C2) joints is warranted if TrPs in the splenius capitis or cervicis muscles are suspected.¹² The most common joint dysfunction seems to be C1-C2, particularly when the splenius capitis muscle is involved. Another common accessory motion dysfunction relating to the splenius capitis muscle is an atlanto-occipital dysfunction (C0-C1). Joint accessory motion dysfunctions at C4 and C5 likely occur with splenius cervicis TrPs.

3.4. Trigger Point Examination

Splenius Capitis

Splenius capitis TrPs can be identified by flat cross-fiber palpation and are usually found near the region where the upper border of the upper trapezius muscle crosses the splenius capitis muscle. The clinician should know the direction of the muscle fibers (Figure 15-2A) and palpate perpendicular to the fibers to find a TrP within a taut band of the muscle tissue. This muscle can be palpated within the small muscular triangle bounded anteriorly by the sternocleidomastoid muscle, posteriorly by the upper trapezius muscle, and inferiorly by the levator scapulae muscle. To locate the splenius capitis muscle, palpate the mastoid process and the prominent sternocleidomastoid muscle. Place one finger posterior and medial to the sternocleidomastoid muscle below the occiput. Then palpate for a contraction of the diagonally directed splenius capitis fibers by asking the patient to turn the face toward the side being examined while extending and extend the head against light resistance provided by the clinician. Once the splenius capitis muscle is identified in this muscular triangle, it can be palpated for taut bands and TrPs. In some patients, the splenius capitis muscle may be taut enough to be clearly palpable without active movement from the patient (Figure 15-3).

Figure 15-3. A, Examination for TrPs in the right splenius cervicis muscle. B, Examination for TrPs in the right splenius capitis muscle.

Another way the muscle can be detected is by first identifying the upper border of the trapezius muscle (Figure 6-1) while the patient is supported in a reclined position with the muscles relaxed. The clinician then palpates for a muscle contraction in the splenius capitis muscle as the patient performs a sudden brief arm abduction movement against light resistance. The splenius capitis muscle is then palpated for taut bands and TrPs along and/or deep to the border of the upper trapezius muscle at approximately the level of the C2 spinous process.

Williams¹⁷ described a splenius capitis TrP at the insertion of the muscle on the mastoid process and in the portion of the muscle just distal to this attachment. According

to Simons et al,¹² the tenderness in this location is more likely to be caused by enthesopathy of the splenius capitis.

Splenius Cervicis

The splenius cervicis muscle is not readily palpable because the upper and middle trapezius muscles cover most of this muscle from behind. Only a small patch of the splenius cervicis muscle is not covered by the splenius capitis or the rhomboid minor muscles posteriorly or by the levator scapulae laterally.

The best method of eliciting tenderness from splenius cervicis TrPs is from the lateral side of the neck through or around the levator scapulae. If the skin and subcutaneous tissues are sufficiently mobile, the clinician slides the palpating finger anterior to the free border of the upper trapezius muscle at approximately the level of the C7 spinous process, toward and beyond the levator scapulae muscle. If the levator scapulae is not tender but additional pressure directed medially toward the spine is painful, it is likely a splenius cervicis TrP. In patients with mobile connective tissue, the taut bands may be palpable running caudally on a diagonal from lateral to medial. To differentiate palpation of the levator scapulae muscle from the splenius cervicis muscle, the levator scapulae muscle can be felt to contract with shoulder elevation, and in contrast, the splenius cervicis muscle contracts with neck extension.

Posteriorly, digital pressure to splenius cervicis TrPs is applied mid-muscle approximately 2 cm lateral to the spine at approximately the level of the C7 spinous process (Figure 15-3), which is just above the angle of the neck. Tenderness mid-muscle, just above the angle of the neck could also result from trapezius TrPs, however, trapezius taut bands are angled laterally, not medially, in the caudad direction. If the tenderness is deep to the trapezius muscle, it may be from either splenius cervicis or levator scapulae TrPs. If cervical flexion increases the sensitivity of the tenderness, it is more likely from splenius cervicis TrPs due to increasing tension on these fibers with flexion. Both the splenius capitis and splenius cervicis muscles are elongated by cervical flexion, but only the splenius capitis is further elongated by flexion of the head on the cervical spine.

In some patients, pressure applied from the lateral aspect of the neck directly toward the spine cephalad to the C7 level elicits tenderness in the region of the cephalad attachments of the splenius cervicis muscle. According to Simons et al,¹² this tenderness is thought to be due to enthesopathy.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. Trigger points may be activated by unaccustomed eccentric loading, eccentric exercise in unconditioned splenius muscle, and/or maximal or submaximal concentric loading.¹⁸ Trigger points may also be activated or aggravated when the muscle is placed in a shortened

or lengthened position for an extended period of time.

A common cause of splenius capitis TrPs is a whiplash injury.^{19,20} These muscles are susceptible to injury due to the trauma of a rear-end collision in an automobile followed by a sudden stop,²¹ especially if the head and neck are somewhat rotated at the time of the impact. Patients with a whiplash injury are known to develop refractory head and neck pain symptoms, probably due to joint injury and TrPs.²² These patients are rarely examined properly and treated for the part of their pain that is of muscular origin. Baker²³ investigated 34 muscles for TrPs in each of 100 occupants (drivers or passengers) who sustained a single motor vehicle impact and identified the direction of the impact. The splenius capitis muscle was the second most frequently involved muscle: in 94% of the subjects in impacts from the front, in 77% of the subjects in impacts from behind, in 75% of the subjects when hit the broadside on the passenger side, and in 69% of the subjects when hit the broadside on the driver's side. In a review of the literature, Fernández de las Peñas et al²⁴ found that TrPs in the scalenes, splenius capitis, sternocleidomastoid,²³ upper trapezius, and pectoralis minor muscles²⁵ were the most affected following a whiplash injury.

Postural, activity-based, and environmental stresses can also activate or perpetuate TrPs in the splenius capitis or cervicis muscles.

Postural stresses include those that overload extension or rotation of the head and neck for prolonged periods of time. Clinical examples include working at a desk with the head turned to one side to view documents or a computer monitor while the body is facing forward; watching planes at an air show while seated in a poor position that extends the neck; using handheld electronic devices while lying prone on elbows (Figure 15-4); and playing musical instruments with poor head and neck positioning, as with the flute or violin. In addition, TrPs in either, or both, the splenius capitis and splenius cervicis muscles may be activated by falling asleep with the head and neck in a laterally flexed position as with the head on the armrest of a sofa without an adequate pillow for support. Cold air from an air conditioner or a cool draft blowing on the exposed neck, together with muscular fatigue, greatly increases the likelihood of activating TrPs in these muscles.¹²

Figure 15-4. Postures that places the splenius cervicis muscles in sustained contraction should be avoided. These activities could include looking up at an air show, bird watching, watching TV from the floor in prone, or using handheld electronic devices while prone on elbows (shown in the figure).

Activity-based stresses that can initiate or perpetuate TrPs in these muscles include pulling on a rope or a heavy object while rotating the head. These muscles, and the levator scapulae muscle, are vulnerable when one pulls excessive weight on exercise pulleys or when one lifts excessive weight; the stress is accentuated when the subject rotates the head and neck and/or projects the head forward. Looking down for prolonged periods of time while texting, playing games on a cell phone, and reading in an unsupported posture can also contribute to the development of TrPs in the splenii muscles. It has been shown that prolonged cervical flexion activates these muscles.¹¹

Environmental stress that can activate both splenius cervicis and levator scapulae TrPs may occur with marked skin cooling, especially when the muscles are tired. An example is exposure to a breeze when a person relaxes in a wet bathing suit in the shade (even on a warm day) after the fatigue of swimming.¹² In other muscles,²⁶ visual stressors have been shown to contribute to the development of TrPs and are plausible for these muscles as well.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas of TrPs.²⁷ Therefore, musculature in the referred pain areas for each muscle should also be considered. Associated TrPs for the splenii muscles can develop in the occipitalis, temporalis, upper trapezius, levator scapulae, semispinalis capitis and cervicis, and suboccipital muscles.

Several other muscles have similar or overlapping pain patterns to the splenius capitis and splenius cervicis muscles, and therefore should be included in the examination and

differential diagnosis. A thorough TrP examination should be performed for the semispinalis cervicis, suboccipitals, levator scapulae, sternocleidomastoid, upper trapezius, temporalis, and deep masseter muscles.

Trigger points rarely appear in the splenii muscles alone; usually, either or both the levator scapulae and other posterior cervical muscles are also involved. If the splenius cervicis muscle is involved without the levator scapulae muscle, cervical rotation is less restricted than when only the levator scapulae muscle is involved. Simultaneous TrP activity in both the levator and splenii muscles may almost completely block active head rotation to that side. Involvement of the splenius cervicis muscle may become apparent because of residual pain and stiffness following the elimination of TrP activity in the levator scapulae muscle.

4.3. Associated Pathology

Trigger points in the splenius capitis muscle are implicated in many head and neck conditions including chronic neck pain,²⁸ mechanical neck pain,²⁹ chronic tension-type headache,^{30,31} episodic tension-type headache,³² upper quadrant pain,³³ and cervical radiculopathy.³⁴ In addition, the presence of active TrPs in the splenius capitis muscle is also frequent in women with fibromyalgia syndrome.³⁵

Currently, there is no research to support involvement of TrPs of the splenius cervicis muscle with other conditions. This evidence deficit is likely due to the difficulty of isolating and accurately palpating the muscle as it was described earlier in this chapter.

Research demonstrates that there is a relationship between TrPs in cervical muscles and cervical joint hypomobility;^{36–38} evidence specifically outlining the involvement of the splenius capitis or splenius cervicis muscles is still needed. Nevertheless, Hsueh et al³⁹ observed that C4-C5 and C5-C6 disc lesions were associated with TrPs in the splenius capitis muscle.

Understanding the clinical presentation of cervical pain is complicated by the similarity of symptoms arising from joint and muscle pathology. A carefully controlled older study showed that painful zygapophyseal joints were present in 54% of 50 consecutive patients with chronic neck pain following a whiplash incident.⁴⁰ More recent evidence has emerged supporting the role of zygapophyseal joint pain in patients with whiplash.⁴¹ These patients were not examined specifically for TrPs, but TrPs frequently coexist with painful articular dysfunctions. The TrPs in the neck muscles and cervical zygapophyseal joints, at corresponding levels, can have remarkably similar pain patterns.⁴² Studies that help clinicians differentiate the cause of the symptoms of cervical pain are still needed. Clinically, treatment of these muscles (in conjunction with the other posterior cervical muscles) with dry needling has improved cervical mobility without performing cervical mobilization or manipulation techniques.

Trigger point involvement of the splenius capitis and cervicis, levator scapulae, upper trapezius and sternocleidomastoid muscles should be distinguished from spasmodic torticollis (cervical dystonia), which is a neurologic condition characterized by involuntary

dystonic movements of the head^{43,44} that can be genetic, acquired, or idiopathic.⁴⁵ The muscles most commonly involved in this condition include the sternocleidomastoid, trapezius, scalenes, and platysma muscles,⁴⁶ therefore making the differential diagnosis of this condition (versus TrPs) essential to ensure proper care. With spasmodic torticollis, hypertrophy of the muscles may develop.⁴³ In contrast, the apparent shortening of a muscle due to TrPs does not cause hypertrophy; nor does it cause involuntary movements of the head. Although physical therapy can be effective for spasmodic torticollis,^{47,48} botulinum toxin is the preferred treatment⁴⁴ because studies have shown the effectiveness of this treatment.^{49–52}

5. CORRECTIVE ACTIONS

Patients with TrPs in the splenii muscles should avoid postural strain by improving their posture. Correction of rounded shoulder posture and forward head position and maintenance of effective posture are primary in any treatment approach both for initial relief of pain and for lasting relief (Figure 6-9). Refer to Chapter 76 for discussions of posture and body mechanics.

Body asymmetry due to a leg length discrepancy or small hemipelvis should be corrected. An excessively long walking cane should be avoided. Neck strain is also avoided by sleeping with the head and neck in a neutral position with appropriate pillow support.

Good ergonomics at work are essential for anyone who spends time at a desk with a computer. It is important to learn how to keep joints in a neutral posture when possible and to minimize excessive twisting and turning movements or prolonged positions with the head turned. The computer screen should be directly in front of the body and at an angle that encourages erect posture while minimizing glare. Documents should be placed on a stand at the same level as the monitor (rather than flat on the desk to one side) for optimum viewing and to avoid excessive muscular strain. Reflections on eyeglasses and contact lenses can be managed by changing the relative position of the light source or by using anti-glare lenses. Patients receiving new progressive lenses should also be evaluated for proper workstation fitting.

Care should also be taken when pulling weights while using exercise equipment. Excessive weight should be avoided, and the patient should learn to pull the weight without rotating the head and neck or protruding the head forward.

Chilling the skin of the neck, especially when the muscles are fatigued, often activates TrPs in posterior neck muscles. The patient should keep the neck warm, when possible, by sleeping in a high-necked sleep shirt, by wearing a turtleneck or scarf during the day, and by avoiding cold drafts.

Posterior Cervical Muscles: Semispinalis Capitis, Longissimus Capitis, Semispinalis Cervicis, Multifidus, and Rotatores

“Iron Man Helmet”

César Fernández de las Peñas and Ana I. de-la-Llave-Rincón

1. INTRODUCTION

The posterior cervical muscles include the middle layers of the cervical spine musculature and the deep cervical extensors. These muscles have attachments from the occiput down to T6. The semispinalis capitis muscle receives innervation from C1-C4, while the semispinalis cervicis receives its innervation from C3-C6. The deeper posterior cervical muscles are innervated by the medial branches of the dorsal rami of the adjacent cervical spinal nerves. These muscles contribute to segmental control of the zygapophyseal (facet) joints of the cervical spine. The main function of the more superficial muscles (ie, semispinalis capitis, longissimus capitis, and semispinalis cervicis) is extension of the cervical spine, whereas the main function of the deepest muscles (ie, multifidus and rotator muscles) is segmental extension and control of the cervical vertebrae. Pain from the semispinalis capitis and longissimus capitis trigger points (TrPs) refers to the head, whereas the multifidus refers pain deep to the cervical spine and sometimes cephalad to the suboccipital region. Activation and perpetuation of TrPs in these muscles can result from acute trauma, especially whiplash, activities that require sustained neck flexion, awkward posture, or positions that place the cervical spine in excessive extension. These muscles can be involved in pain syndromes of the cervical spine, particularly in mechanical neck pain or along with cervical radicular pain or radiculopathy. The semispinalis capitis muscle is more frequently affected by TrPs in patients with whiplash than in individuals with fibromyalgia syndrome. In addition, morphologic changes in these muscles have been observed in patients with cervical spine disorders. Specifically, fatty tissue infiltration of the multifidus muscles has been found in patients with whiplash-related neck pain. Also, patients with mechanical neck pain demonstrate reduced activation of the multifidus and semispinalis

cervicis muscles as well as decreased cross-sectional areas of cervical multifidus. Corrective actions of this muscle group include optimizing posture to reduce gravitational stress and temporary use of a soft collar for support.

2. ANATOMIC CONSIDERATIONS

The posterior neck muscles are divided anatomically into four layers with fibers running in different directions at some levels,¹ suggesting the plies of a tire (Figure 16-1). The most superficial layer, the bilateral upper trapezius, converges above, tending to form a “^” or roof-top shape. The next deeper layer, the bilateral splenius fibers, converges below to form a “V” shape. The semispinalis capitis fibers of the third layer lie nearly vertical, parallel with the vertebral column. All the remaining innermost layers of fibers return to the “^” configuration. These include the more deeply placed semispinalis cervicis of the third layer and the multifidus and rotators fibers which constitute the fourth layer. Knowledge of this fiber arrangement is helpful to treat these muscles effectively. The erector spinae muscles of the cervical spine include the longissimus capitis and cervicis, iliocostalis cervicis, and the variable spinalis capitis and cervicis muscles.²

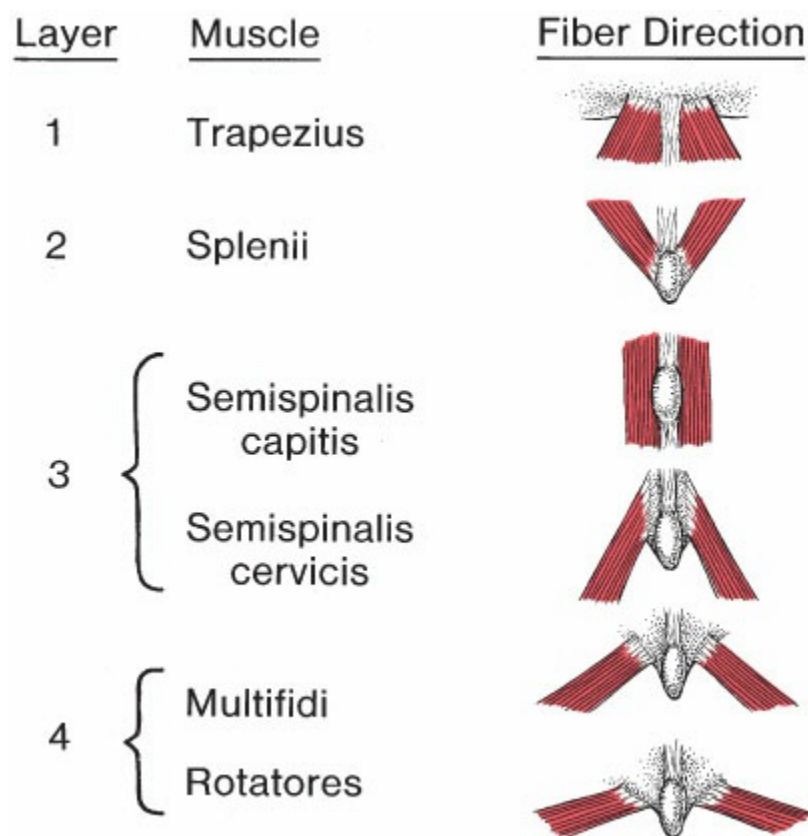

Figure 16-1. The changes in the directions of successively deeper fibers in the four layers of the posterior cervical muscles with layer 1 representing the most superficial muscle fibers and layer 4 the deepest fibers.

Functionally, these muscles can be categorized in two groups: four muscles that attach

and control the movement of the head (upper trapezius, splenius capitis, semispinalis capitis, and longissimus capitis muscles), and three muscles that have only spinal vertebral attachments and do not act on the head (semispinalis cervicis, multifidus, and rotatores muscles). Digitations of the second group of muscles attach at each vertebral segmental level and analogous digitations extend throughout the thoracic region and into the lumbar region with basically the same arrangement. At successively greater depth, muscles of this group become shorter and more angulated.

The anatomic designation of the second functional group of muscles to three names, that is, semispinalis, multifidus, and rotatores, is quite arbitrary. In fact, there is a full and continuous transition of lengths at each spinal level. Digitations attaching at every vertebra span 0 to 5 vertebral segments.²

Semispinalis Capitis

The semispinalis capitis muscle lies superficial over the semispinalis cervicis muscle. This muscle originates on the medial aspect of the area between the superior and inferior nuchal lines of the occipital bone forming a thick muscle bundle in the suboccipital region and inserts onto the superior articular processes of C4-C7 and the tips of the transverse processes of T1 to T6 and sometimes T7 (Figure 16-2).² The semispinalis capitis muscle is usually divided by a tendinous inscription at the level of C6 vertebrae. These inscriptions divide the muscle into thirds, each with an endplate zone. The endplate zone of the upper third of the semispinalis capitis muscle is aligned nearly transversely at the suboccipital level. The endplate zone of the middle third is found at approximately the C3-C4 level. Due to the differing fiber lengths in the most inferior third of the muscle, this endplate zone is more variable.

Figure 16-2. Attachments of the posterior cervical muscles. Left side, the fibers of the longissimus capitis and semispinalis capitis muscles (medium red) lie almost vertical, between the skull and the thoracic vertebrae. The semispinalis cervicis muscle is not shown here. It is intermediate between the semispinalis capitis and multifidus muscles in depth,

fiber length, and angulation of fibers. Right side, the deepest layer, comprised of the multifidus (light red) and rotatores muscles (dark red). They travel diagonally to bilaterally form, the roof-top \wedge shape.

The greater occipital nerve can be trapped by a tendinous band of the semispinalis capitis muscle, or as it passes through the semispinalis capitis muscle, traveling between its most medial fibers and the nuchal ligament (Figure 16-3).³ The greater occipital nerve is the medial branch of the dorsal primary division of the second cervical nerve and supplies sensory branches to the scalp over the vertex as well as motor branches to the semispinalis capitis muscle. This cervical nerve emerges below the posterior arch of the atlas above the lamina of the axis (Figure 16-3). It then curves around the lower border of the oblique capitis inferior muscle which it crosses before penetrating the semispinalis capitis and trapezius muscles near their attachments to the occipital bone.

Figure 16-3. Course of the second cervical nerve which becomes the greater occipital nerve and then penetrates the semispinalis capitis (light medium red) and trapezius muscles (light red) to continue beneath the scalp. Entrapment can occur where the nerve passes through the semispinalis muscle. Note the vertebral artery (darkest red) in the suboccipital triangle which is bounded by the rectus capitis posterior major and the oblique capitis superior and inferior muscles (dark medium red).

In an autopsy study of 20 cases (40 nerves) without a history of headache (according to hospital files), the greater occipital nerve penetrated the trapezius muscle in 45% of the

cases, the semispinalis muscle in 90% of the cases, and the inferior oblique muscle in 7.5% of the cases.⁴ Eleven of the 18 nerves that penetrated a trapezius muscle showed evidence of compression. This finding was unexpected because the selection was made on the basis of no established history of headache (according to hospital charts). Apparently, some degree of nerve compression at the point of a trapezius muscular penetration is common.⁴

Longissimus Capitis

The longissimus capitis muscle (Figure 16-2) originates at the posterior edge of the mastoid process, deep to the splenius capitis and sternocleidomastoid muscles, and inserts onto the transverse processes of C5-C7 and T1-T4 vertebrae.² It descends across the lateral surface of the semispinalis capitis muscle. The longissimus capitis muscle is often partially or completely divided into two muscle bellies by a tendinous inscription.

Semispinalis Cervicis

The semispinalis cervicis muscle (not illustrated here) lies deep to the semispinalis capitis muscle and originates from the spinous processes of C2 to C5 vertebrae and inserts into the transverse processes of T1 to T5.² Its fascicles span about six segments and cover the cervical and thoracic multifidus muscles. The diagonal orientation of the digitations of this muscle can be seen in Figure 16-1.

Multifidus and Rotatores

The cervical multifidus is formed by several fascicles originating from the caudal edge of the lateral surface of the spinous process and from the caudal end of the spinous process of C2 to C5 vertebrae and inserting onto the transverse process of vertebrae two, three, four, and five levels below (Figure 16-2).² The fascicles from a given segment are flanked and overlapped dorsolaterally by fascicles from successively higher segments, an arrangement that endows the intact muscle with a laminated structure. The cervical multifidus is the deepest muscle spanning the lamina of the vertebrae, and it directly attaches to the capsules of the cervical zygapophyseal joints.⁵ These muscles, therefore, contribute to the segmental control of the zygapophyseal joints of the cervical spine.⁶

The cervical muscles, when present, also originate at C2 and extend downward segmentally. In each segment, a rotator brevis muscle originates from the lower border of the lateral surface of the lamina above and inserts onto the upper, posterior part of the transverse process of the vertebra immediately below. Additionally, a rotatores longus muscle connects the base of the spinous process above to the transverse process two levels below.² They are the shortest and deepest paraspinal muscles, connecting adjacent or alternate vertebrae, and therefore, are the most angulated (Figures 16-1 and 16-2). The degree of angulation of these muscles has important functional implications.

2.1. Innervation and Vascularization

The semispinalis capitis muscle is supplied by branches of the posterior primary division of the first 4 or 5 cervical spinal nerves (C1-C4), and the semispinalis cervicis muscle is supplied by the third to sixth cervical spinal nerves (C3-C6). The longissimus capitis muscle and the deeper posterior cervical muscles are supplied by the medial branches of the dorsal rami of the adjacent cervical spinal nerves. The dorsal muscles of the cervical spine receive their blood supply from the vertebral artery, deep cervical artery, superficial and deep descending branches of the occipital artery, and deep branch of the transverse cervical artery, when present.²

2.2. Function

Functions of the semispinalis capitis muscle primarily relate to head movement; whereas the deeper intervertebral muscles are primarily concerned with stabilization and segmental movement of the cervical vertebrae.⁷

Semispinalis Capitis

The semispinalis capitis muscle has one main action, extension of the head, and it functions in antigravity control of the head when one leans forward. Electrical stimulation of the semispinalis capitis muscle produces head extension and slight inclination to the same side but not neck extension.⁸ Nevertheless, the role of semispinalis capitis muscle in rotation is controversial because the assumption that all posterior muscles act synergistically as extensors is not clear.⁸

An older electromyographic (EMG) study using fine-wire electrodes in 15 subjects, reported that the semispinalis capitis muscle responded vigorously during the extension of the head and neck, but with training, electrical silence could be achieved while the head and neck were held in the erect, balanced position. Electrical activation of these muscles in support of the head appeared only during body activity that disturbed the balance of the head on the body.⁹ Also, no EMG activity was observed in this muscle during lateral flexion of the head and during head rotation.

No study was found that specifically examined the slightly forward-flexed head posture commonly assumed for reading. The exercise data strongly suggests that the semispinalis capitis muscle consistently provides a checkrein function during even a slight flexion of the neck⁹ which has been well demonstrated for the erector spinae muscles at the lumbar level. Abuse of this checkrein activity is a major cause of the frequently observed chronic strain of the posterior cervical muscles.

Longissimus Capitis

The longissimus capitis muscle is a head on neck extensor that is also reported to laterally flex the head to the same side and rotate it toward the same side.

Semispinalis Cervicis

The semispinalis cervicis muscle is reported to primarily extend the cervical spine and rotate it the opposite side.⁸ The caudal insertion to the relatively immobile thoracic vertebrae serves primarily to stabilize the movement of the cervical spine. A study by Pauly⁹ suggests that the semispinalis cervicis muscle, at times, provides a checkrein function during even a slight flexion of the neck.

Multifidus and Rotatores

Evidence clearly describing the functions of this group of muscles, specifically for the cervical area is lacking, but generally, when acting bilaterally, these deep muscles, extend the vertebral column. Acting unilaterally, they rotate the vertebrae to the opposite side. The multifidus muscles were identified as contributing to lateral flexion of the spine. Anderson et al⁵ found that the total moment-generating capacity of the cervical multifidus muscles, in the neutral posture, was predicted to be approximately 0.7 Nm for extension and lateral bending and 0.3 Nm for axial rotation. However, these deeper muscles seem to be designed for control and are said to control positional adjustments between vertebrae, rather than movements of the spine as a whole.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 16-1 grossly represents the functional unit of the posterior cervical muscles.¹⁰

Box 16-1 Functional unit of the posterior cervical muscles

Action	Synergists	Antagonist
Head extension (Semispinalis capitis and Longissimus capitis)	Suboccipital muscles (bilaterally) Upper trapezius Splenius capitis muscles	Cervical head flexors Rectus capitis anterior Sternocleidomastoid (bilaterally)
Neck extension (Semispinalis cervicis)	Splenius cervicis (bilaterally) Longissimus cervicis Semispinalis capitis Levator scapulae	Anterior neck muscles Longus colli

(bilaterally) Multifidus (bilaterally)

For rotation of the neck, the semispinalis cervicis muscle functions synergistically with the contralateral splenius cervicis and levator scapulae muscles, and with the ipsilateral multifidus and rotatores muscles.

During combined extension and rotation of the neck, the multifidus and rotatores muscles act synergistically with the semispinalis cervicis muscle. For each separate movement, synergists and antagonists are the same as those previously listed above for the semispinalis cervicis muscle.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Semispinalis Capitis

Pain elicited from TrPs of the semispinalis capitis muscle refers to the head (Figure 16-4). Clinically, it has been observed that the upper portion of the muscle can refer pain to the skull traveling forward like a band and encircling the head halfway, reaching maximum intensity in the temporal region, and continuing forward over the eye (Figure 16-4B). The middle portion of the muscle can spread deep pain more posterior on the skull (Figure 16-4C). In fact, referred pain of the middle and lower parts of the semispinalis capitis muscle and the referred pain of the semispinalis cervicis muscle overlap with part of the pain distribution of the C2-C3 zygapophyseal joints.¹¹

Figure 16-4. Referred pain patterns (red) from posterior cervical muscles. A, The semispinalis capitis muscle; B, Referred pain pattern from TrPs in the upper portion of the semispinalis capitis muscle. Trigger points in the upper third of the muscle can contribute to entrapment of the greater occipital nerve; C, Referred pain pattern of TrPs in the middle portion of semispinalis capitis muscle. The semispinalis cervicis muscle can also refer pain in a similar pattern; D, Referred pain pattern of the deeply placed cervical multifidus TrPs.

Longissimus Capitis

Pain from the longissimus capitis muscle (not illustrated) concentrates in the region of the ipsilateral ear or just behind and below it. The pain may extend a short distance down the

neck and may also include pain in the periorbital region.

Semispinalis Cervicis

The referred pain from semispinalis cervicis TrPs is not illustrated separately because this muscle likely refers pain to the occipital region in a pattern similar to that shown in Figure 16-4 for the middle portion of semispinalis capitis muscle.

Cervical Multifidus

Trigger points from cervical multifidus muscles refer pain and tenderness cephalad to the suboccipital region and sometimes down the neck to the upper vertebral border of the scapula (Figure 16-4D).¹² Similar pain patterns have been produced by injection of hypertonic salt solution into the posterior cervical muscles.¹³ The pain arising from the cervical multifidus muscles sometimes is related to cervical zygapophyseal joints on the same segment and can mimic deep localized pain around the spinous process.

Rotatores

When present, TrPs of cervical rotatores muscles produce midline pain and tenderness at the segmental level of the TrP. Pain is elicited by application of pressure or tapping on the spinous process of the vertebra to which the muscle attaches. This tenderness testing is also used to identify dysfunctional joints and differentiation can be difficult.

3.2. Symptoms

Patients reporting pain in the head elicited by cervical muscles are likely to be referred with the diagnosis of tension-type headache¹⁴ or cervicogenic headache.¹⁵ These muscles are also involved in individuals with whiplash-associated disorders¹⁶ or mechanical neck pain.¹⁷ With chronic headache sufferers, the pain pattern is likely to be a composite of referred pain from several neck and masticatory muscles (see Figure 17-1).

Patients are likely to be bothered by tenderness over the back of the head and neck so much so that pressure at that point from the weight of the head on a pillow at night may quickly become intolerable. Some degree of painfully restricted neck motion in one or more directions, especially head and neck flexion, is typical.

With entrapment of the greater occipital nerve as a sequela to prolonged activation of a semispinalis capitis or upper trapezius muscles, patients may report numbness, tingling, and burning pain in the scalp over the ipsilateral occipital region (“occipital neuralgia”) in addition to headache. They may have received anesthetic blocks of the greater occipital nerve with relief only for the duration of the local anesthetic effect. Patients with nerve entrapment usually prefer cold rather than heat to relieve the burning neuropathic pain; this relief can also obscure the TrP pain. Entrapment symptoms of the greater occipital nerve may develop when TrP activity in one of the muscles that it penetrates (the semispinalis capitis or the upper trapezius muscles) produces taut bands of muscle fibers

that compress the nerve.

The symptoms associated with entrapment of the greater occipital nerve are often relieved by the inactivation of TrPs in the semispinalis capitis and/or upper trapezius muscles.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change.

Patients with posterior cervical TrPs often hold the head and neck upright with the shoulders high and rounded; they may position the head with the face tilted up somewhat and tend to suppress the bobbing and nodding movements of the head that ordinarily accompany talking.

The patient usually demonstrates marked restriction of head and neck flexion, which can measure 5 cm short of the chin reaching the sternum. Altered segmental motion of the cervical spine with palpation is a common finding associated with muscular dysfunction. Marked restriction of head and neck rotation and cervical side-bending is usually due to the involvement of associated cervical muscles. In any one segment however, restriction in all directions likely indicates a capsular (or arthritic) pattern.

If involvement of the posterior cervical muscles is mainly unilateral and the head and neck are flexed, the muscles on the painful side may appear very prominent like a rope from the skull to the level of the shoulder girdle.

3.4. Trigger Point Examination

Semispinalis Capitis

Trigger point palpation of posterior cervical muscles is based on the proper knowledge of anatomy and the expected locations of the muscle because these muscles are not directly palpated. Slight flexion of the head and neck increases tension of the taut bands and the tenderness of TrPs in the posterior neck muscles. Trigger points are more easily identified by palpation if the posterior cervical musculature is relaxed by providing adequate head and body support for the patient in the seated or the side-lying position. All posterior cervical muscles are best examined using a flat cross-fiber palpation. It is often very difficult to elicit a detectable local twitch response by manual palpation of this muscle. However, if the upper trapezius muscle is relaxed, one may be able to palpate a taut band in the semispinalis capitis muscle that is distinguished by its vertical fiber direction.

Trigger points in the upper portion of the semispinalis muscle (Figure 16-4) are likely to feel indurated and often need to be pressed very firmly to elicit referred pain. Therefore, deep tenderness on examination is much less intense than would be expected from the severity of the patient's pain complaint. This region of tenderness is usually found at a

distance of a centimeter or two from the midline at the base of the skull and is also in the region of one of the controversial tender point sites used to diagnose fibromyalgia syndrome, discussed in the following.¹⁸

Longissimus Capitis

The longissimus capitis muscle lies deep to the lateral part of the splenius capitis muscle near the level of the C3 vertebra. From the level of the C2 spinous process to the junction of C3-C4, clinicians can attempt to palpate TrPs and taut bands of the longissimus capitis muscle by locating the splenius capitis muscle (lateral to the trapezius muscle and posterior to the sternocleidomastoid muscle), and by pressing anteriorly and medially through the lateral part of the splenius capitis muscle. If the splenius capitis muscle has TrPs and taut bands they should be first released or the deeper tenderness of the longissimus capitis TrPs may not be distinguishable. If the longissimus capitis muscle has TrPs, it will present as prominent and firm, and its nearly vertical fibers will help distinguish it from the more diagonal fibers of the splenius capitis muscle. Superior to the level of C2 and inferior to the level of C4, the longissimus capitis muscle is too deep and covered by too many other muscles to be reliably identified, even indirectly.

Semispinalis Cervicis

Palpation for TrPs of this intermediate-to-deep posterior cervical muscle is possible 1 to 2 cm lateral to the spinous processes. Trigger points are commonly found at approximately the C4-C5 level, and deep pressure on the TrP may elicit referred pain over the occipital region similar to the pattern shown in Figure 16-4. Only rarely can one distinguish taut bands in this relatively deep muscle.

Figure 16-5. Possible locations (many may not be palpable) of TrPs in posterior cervical muscles based on clinical experience and expected locations of endplate zones for posterior cervical muscles. Segmental levels correspond to spinous processes (or the posterior tubercle of C1). All these locations should be considered as a guide, because the entire muscle belly should be searched for the presence of TrPs.

Cervical Multifidus and Rotatores

Trigger points of cervical multifidus muscles can be located approximately halfway between a spinous process and a lower transverse process, usually 1 cm lateral to the spinous process. Because there are digitations of the cervical multifidus muscles for every segmental level from C2 inferiorly and because some digitations span more than one vertebra, TrPs in the cervical multifidus muscles could be found at any level between these processes starting at about the interface between spinous processes C3 and C4 and continuing inferiorly as thoracic multifidus. Manual palpation of this muscle, based on anatomic landmarks, may be limited because they form the deepest layer of the posterior cervical musculature.

The deepest muscles, the rotatores, are often not as fully developed in the cervical region as they are in the thoracic region. These muscles lie too deep for the fiber direction of their taut bands to be identified by palpation. They should be identified by characteristic deep tenderness to the pressure applied deep in the groove lateral to spinous processes and by tenderness to pressure or tapping at the spinous process. The pain distribution of the rotator muscles is essentially a midline pain at the segmental level and deep, simulating pain into the spinous process (bone pain).

Locations of TrPs in posterior cervical muscles are summarized in Figure 16-5. Because TrPs may form at any location throughout each muscle, a thorough examination is required for proper identification of TrPs.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the posterior cervical muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.¹⁹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Many kinds of events can activate TrPs in the posterior cervical muscles, but other factors are required to perpetuate them. For instance, acute trauma can activate TrPs in these muscles. Falling on the head, experiencing forceful head movement in an automobile accident, or diving headfirst and hitting the head can produce forceful neck flexion and muscle strain which can activate TrPs in head and neck muscles even in the absence of fracture. Baker²⁰ examined 34 muscles bilaterally of 100 occupants (drivers or passengers) who sustained a single motor vehicle impact. All these patients complained of whiplash-

associated disorders and all had active TrPs. The semispinalis capitis muscle was the third most frequently involved muscle with dysfunction present in 73% of subjects who reported impact from the front, in 69% of subjects who experienced impact on the passenger side, in 63% of subjects who experienced impact on the driver's side, and in 62% of subjects in vehicles struck from behind. Therefore, automobile impact from any direction is likely to activate semispinalis capitis TrPs.

Other factors can perpetuate the presence of TrPs in the posterior cervical muscles. A chronically activated stress response that eventually activates TrPs, if continued, also perpetuates them. Strain from ineffective posture, such as from reading or working at a desk while sitting with a forward head posture or with the neck in sustained flexion, commonly activates and perpetuates posterior cervical TrPs. Refer to Chapter 76 for proper posture and ergonomic set up to avoid activation and perpetuation of posterior cervical TrPs.

Excessive cervical extension at night tends to activate and perpetuate TrPs in the posterior cervical muscles by placing these muscles in a shortened position for a prolonged period. This posture occurs when a person lies supine without a pillow on a mattress that is too hard or when a too-hard, poorly fitted pillow is placed under the shoulders and neck. Sometimes young people (in particular) lie prone on the floor, propped up on elbows to support the head, while watching television. This position places the posterior cervical muscles in a shortened position for a prolonged period of time and may activate or perpetuate TrPs of the posterior cervical muscles.

Since the more longitudinal posterior cervical muscles commonly function bilaterally, TrP involvement of one side soon leads to at least some functional disturbance of the contralateral muscles which can activate TrPs in them also.

4.2. Associated Trigger Points

In addition to the bilateral posterior cervical muscles, the upper semispinalis thoracis and the erector spinae muscles that extend into the thorax may demonstrate TrPs associated with those found in the posterior cervical muscles. The segmental level of TrP involvement can be identified by a *flattened spot* in the normally smooth curvature of the thoracic region; when tested by voluntary forward flexion, at least one spinous process fails to stand out prominently as expected. Multiple bilateral deep short rotator muscles can look like the longer but less angulated multifidus muscle in this respect; however, multifidus muscle involvement would not cause as much restricted rotation as the rotator muscles do, and the multifidus muscle is less likely to cause a continuous series of pressure-sensitive vertebrae with restricted joint mobility. Manual techniques designed to improve both joint and muscle functions may be effective.

When the posterior cervical muscles have been treated and patients continue to complain of suboccipital pain and soreness, especially in the region of the mastoid process, the clinician should check for active TrPs in the trapezius muscle, in the posterior belly of the digastric muscle, and in the upper medial portion of the infraspinatus muscle on the

same side as the pain. Trigger points in the latter two muscles cause little restriction of head motion and are easily overlooked.

Hong²¹ pointed out that the semispinalis capitis muscle may develop associated TrPs in response to TrPs in either an upper trapezius or splenius capitis muscles. Elimination of TrPs in either of these two muscles usually inactivates the TrPs of the semispinalis capitis muscle without any specific treatment of the semispinalis capitis muscle itself. Conversely, inactivating only the associated TrP results in its reactivation and perpetuation by the TrP in the primarily involved muscle.

4.3. Associated Pathology

The location of the posterior neck muscles overlaps with “tender points” used for the diagnosis of fibromyalgia syndrome.¹⁸ A brief examination of the designated tender points of fibromyalgia and associated widespread and fatigue-related symptoms assists in the exclusion or establishment of a correct diagnosis. Patients with fibromyalgia commonly have myofascial TrPs that contribute to their pain.²² Finding a positive occipital tender point should alert the clinician to the possibility of an enthesopathy secondary to a semispinalis capitis TrPs.

Clinically, cervical radicular pain or radiculopathy can activate TrPs in the posterior cervical muscles that, following surgery, are then perpetuated by other factors. This is a common cause of cervical post-laminectomy pain syndromes.²³ Because the radicular pain and the TrPs can occur separately or concurrently, each condition should be diagnosed based on its own criteria.²⁴ Cervical radicular pain or radiculopathy from C4 to C8 rarely fails to cause upper extremity signs or symptoms. Posterior cervical TrPs alone do not produce upper extremity symptoms. Cervical radicular pain or radiculopathy is much more likely to show a positive *Spurling test*, pain elicited by spinal compression applied as a downward pressure on the head with the upright cervical spine slightly extended. Positive electrodiagnostic findings are helpful in identifying cervical radiculopathy.

One should distinguish between the local neurologically projected pain of a Tinel’s sign (produced by tapping on the point of entrapment) and referred pain from a TrP. The shock-like tingling or “pins and needles” of the Tinel’s sign is produced by pressure on a point of constriction, for example, where the greater occipital nerve passes through the semispinalis capitis muscle or upper trapezius muscle (Figure 16-3). Neural pain is usually projected along the distribution of the nerve. In comparison, TrP referred pain is usually described as a deep aching pain that is less well localized and has a nonneural distribution. Trigger points respond to snapping palpation with a local twitch response of the taut band. Injections at the point of neural entrapment should be avoided, whereas injection of the TrP in the muscle that contributes to the entrapment is an appropriate therapy.

Inflammatory disorders of the neck have the potential to cause erosions at the atlantoaxial (AA) articulation which can progress to lysis of the transverse ligament and subluxation of the odontoid process of C2. In addition to a careful history and clinical examination for systemic disease, a person suspected of having symptomatic arthritic

involvement of the neck should have imaging confirmation. A pair of lateral neck radiographs, in voluntary flexion and extension, can help identify inappropriate motion (>4 mm) of the odontoid process away from the internal margin of the ring of C1. Imaging of subaxial disease requires computed tomography with contrast, magnetic resonance imaging, or even myelography. Halla and Hardin Jr²⁵ identified a distinctive clinical syndrome in 27 patients with C1-C2 facet joint osteoarthritis. Occipital TrPs were one of the major features of the syndrome. This syndrome was seen mainly in elderly women who also have osteoarthritis at other sites and who experienced occipital and post-auricular pain. Physical signs included limited head rotation, tender points or TrPs confined to the occipital area, palpable cervical crepitus, and abnormal head position to one side.²⁵ The crepitus of the C1-C2 arthritis and taut bands with recognition of pain on palpation of TrPs would be the two most clearly distinguishing characteristics. This strong association between cervical osteoarthritis and myofascial TrPs is compatible with the observation of Jaeger¹⁵ who found the semispinalis capitis muscle to be one of the most frequently involved. Hence, cervical osteoarthritis is likely to activate and/or perpetuate cervical myofascial TrPs. In fact, Bogduk and Simons¹¹ have reported overlapping pain patterns of cervical zygapophyseal joints and posterior cervical muscles. The C2-C3 zygapophyseal joints in particular need to be considered in diagnosis when dealing with TrPs in the semispinalis capitis and semispinalis cervicis muscles. The C3-C4 and C4-C5 zygapophyseal joints refer pain in patterns that overlap partly with the pain distribution of cervical multifidus TrPs. It is possible that other arthritic conditions such as rheumatoid arthritis and seronegative spondyloarthropathies may have a similar influence on cervical TrPs.

The *seronegative* (meaning negative blood rheumatoid factor test) *spondyloarthropathy* disorders can include ankylosing spondylitis, Reiter's syndrome, reactive arthritis due to inflammatory bowel disease, or reactive arthritis associated with psoriasis.²⁶ A typical pathologic process in these patients is painful enthesopathy (inflammation at the site of attachment of ligament or tendon to bone) which tends to heal with diastrophic calcification. In ankylosing spondylitis, the spinal ligaments tend to calcify symmetrically from the sacroiliac joints upward until the entire spine is fused into what appears on x-rays like a vertical stick of bamboo (the so-called bamboo spine). In the other disorders such as Reiter's syndrome, the inflammatory involvement of the axial skeleton tends to be more asymmetric (skipping vertebral levels and involving only one side of some vertebrae). In any of these conditions, neck pain can be a prominent symptom, and involvement of the AA joint can place the spinal cord at a risk of serious injury. The presence of systemic symptoms, such as conjunctivitis and urethritis in Reiter's syndrome, can be helpful in establishing the correct diagnosis.

Two older studies reported palpatory spasm (or TrP contracture), tissue texture changes, and cervical restricted motion at C1-C3, assumed to be secondary to viscerosomatic reflexes from cardiac, upper gastrointestinal, and pulmonary disorders.^{27,28}

4.4. Associated Cervical Joint Dysfunctions

When exploring the differential diagnosis of neck pain, one should consider a wide variety of cervical joint disorders that can cause symptoms in the cervical area but are usually diagnosed on the basis of patterns of involvement at other sites in the body. Fernández de las Peñas et al²⁹ observed a clinical association between the presence of TrPs in the neck muscles and cervical joint dysfunction in the innervation-related segment. Satisfactory management of head and neck pain of musculoskeletal origin often requires careful evaluation of posterior cervical muscles for TrPs and cervical joints for restricted mobility. Often both of these findings are present, and frequently both should be treated.

Jaeger¹⁵ examined each of 11 patients, with symptoms of cervicogenic headache, for TrPs in seven head and neck muscles and for cervical spine dysfunction. All patients had at least three active myofascial TrPs. In eight patients, TrP palpation clearly reproduced the headache. Ten of the 11 patients (91%) had a specific segmental dysfunction of the atlanto-occipital (AO) joint or of the AA joint. The temporalis muscle was the one most likely to have TrPs (n = 7), and the semispinalis capitis muscle was the next most likely (n = 6). Trigger points were predominantly found on the most symptomatic side. Among the posterior cervical muscles, suboccipital articular dysfunction was most likely to be associated with TrPs in the semispinalis capitis muscle.

Semispinalis capitis TrPs are frequently associated with OA, C1, and C2 dysfunctions. Longissimus capitis TrPs can be associated with an apparent elevation of the first rib concurrent with T1 articular dysfunction. Part of this muscle spans the region from the mastoid process to the transverse process of T1, which allows it to *indirectly* affect the first rib through its pull on the costotransverse junction. Resultant rotation of the vertebra produces the *apparent* rib elevation. The semispinalis cervicis, multifidus, and rotators muscle groups can form articular dysfunctions at various levels of the cervical and upper thoracic spine depending on the specific attachments.

A simple extension dysfunction of T1, T2, T3, and T4 segments is another important articular dysfunction associated with TrP involvement of bilateral posterior cervical muscles that attach to or span the upper thoracic vertebrae. This is particularly true of the semispinalis cervicis, multifidus, and rotator muscles with attachments in the upper thoracic region as well as the semispinalis thoracis digitations that extend to and cross these upper thoracic vertebral segments. The upper thoracic segments are particularly difficult to isolate. One should, however, treat these extension dysfunctions from T1 to T4 by using a manual stretch technique that also incorporates contract-relax and forward flexion progressing down the spine segment by segment.

5. CORRECTIVE ACTIONS

Chronic strain activates posterior cervical TrPs because these muscles control the weight of the head when it is held in partial flexion for prolonged periods. Optimizing posture to reduce gravitational stress³⁰ or improvement of biomechanical/ergonomic function reduces this strain. Refer to Chapter 76 for a full discussion of postural considerations. Corrections include the following:

1. Use of a reading stand or adjustable music stand to change the angle of, or to raise, the reading and work materials to approximate eye-level contact to avoid sustained flexion of the head and neck.
2. Elevation of the computer monitor when it requires a downward gaze and is used for prolonged periods.
3. Procurement of eyeglasses with adequate focal length, so that the patient can see clearly with the head held in a balanced upright position. Otherwise, a new prescription for longer focal length lenses (“card playing or computer glasses”) should be obtained.
4. Selection of bifocal or transitional lenses that are large enough to allow for effective head posture for close work such as reading or sewing.
5. Adjustment of eyeglass frames so that the lower portion of the rim does not occlude the line of sight on looking down.
6. Alteration of exercise posture on a stationary bicycle by sitting upright with the arms swinging freely or placed on the hips and *not* hunched over holding low handlebars that do not steer the machine.
7. Addition of a cloth roll or pillow behind the thoracolumbar junction while sitting to maintain the normal lumbar lordotic curve and lift the sternum, improving the head and neck posture.
8. Inactivation of pectoralis major or minor TrPs (refer to Chapters 42 and 44) that induce rounded shoulder posture and a functional thoracic kyphosis.
9. Alteration of laptop behaviors. The use of laptops for on-the-go computer work can be problematic for maintaining balanced head posture. If the laptop is at the level of the eyes, the shoulders are likely to elevate to allow for typing. If the laptop is placed low so that the arms may be in contact with armrests or a table at the height of a bent elbow, the head and neck should flex to see the screen. Use of a portable keyboard to separate functions of the hands and eyes allow for improved posture of both the upper quadrants and the head and neck.

These last two corrections permit the erect head and neck to assume a balanced relaxed position over the thoracic spine. In summary, the patient should comfortably maintain a balanced head posture.

Another simple correction to promote erect balanced sitting posture is provided by placing a small pad under the ischial tuberosities. The pad should *not* extend under the upper thigh.

Excessive cervical extension at night is corrected by obtaining a slightly softer (nonsagging) mattress or by using a small soft neck pillow that comfortably supports the normal cervical curve. Chattopadhyay³¹ described the rationale and importance of a well-fitting cervical pillow. A versatile and adaptable pillow that places the head and neck in a neutral position may be indicated.

The neck muscles of patients with posterior cervical TrPs may be particularly

vulnerable to chilling and if so, can be kept covered at night by a turtleneck sweater worn in bed or by a loose scarf draped around the neck. Similarly, the neck should be protected from cold drafts during the day. Long hair offers natural protection against this cold exposure.

To temporarily relieve neck strain after an acute exacerbation, one may prescribe a soft collar to be worn loosely as a *chin rest* when riding in a car or working at a desk (Figure 16-6). The collar is NOT tightly adjusted for immobilization of the neck but applied loosely. For instance, a Thomas plastic collar may be worn upside down and loose enough to allow space for head rotation and to look down at the sides, yet tight enough to support the chin so that the head is in the neutral position.

Figure 16-6. A soft collar may help relieve stress on posterior neck muscles when seated in the car or at a desk. It should be worn loosely as a chin rest and not for immobilization of the neck.

Suboccipital Muscles

“Mask of Zorro”

Michael Karegeannes, César Fernández de Las Peñas, and Michelle Finnegan

1. INTRODUCTION

The suboccipital muscles include the rectus capitis posterior major, rectus capitis posterior minor, obliquus capitis superior, and obliquus capitis inferior muscles. They connect the occipital bone, atlas, and axis posteriorly. They are innervated by the branches of the dorsal primary division of the suboccipital (C1) nerve. These muscles contribute to dynamic stability of the upper cervical spine by assisting with proprioception of the head with a high muscle spindle count. They also contribute to small movements of the head on the neck. The referred pain from suboccipital trigger points (TrPs) is felt deep inside the head, to the occiput, temporal region, eye, and forehead. Activation and perpetuation of TrPs in this muscle group can result from awkward posture, improperly fitted eyeglasses, prolonged position of the head held in rotation to one side, and trauma. Trigger points in these muscles are commonly associated with tension-type headache, cervicogenic headache, occipital neuralgia, or chronic intractable benign pain. Corrective actions include postural correction, ergonomics assessment, strengthening, and self-stretching.

2. ANATOMIC CONSIDERATIONS

Rectus Capitis Posterior Minor

The rectus capitis posterior minor muscle originates by a narrow pointed tendon in the tubercle on the posterior arch of the atlas and attaches to the medial part of the inferior nuchal line and to the occipital bone between the inferior nuchal line and the foramen magnum¹ (Figure 17-1). Recently, this muscle was found to be absent in a subject bilaterally.² Hack et al³ first reported the existence of a connective tissue bridge between the rectus capitis posterior minor muscle and the cervical dura at C0-C1 levels. Additional anatomic studies have confirmed the existence of the anatomic connection between this muscle and the cervical dura at C0-C1 vertebral level.⁴⁻⁶ Histologic analysis revealed that

this anatomic connection fuses with the posterior atlanto-occipital membrane, which ultimately coalesces with the cervical spinal dura.⁵ In fact, it is one of the muscles with almost the highest number of muscle spindles.⁷

Figure 17-1. Attachments of the suboccipital muscles (medium red). The most lateral three of these four muscles define the suboccipital triangle. This triangle surrounds the transverse portion of the vertebral artery (dark red) and should be avoided when needling the posterior neck muscles. The more superficial overlying muscles are light red. The black dotted lines indicate the location of the attachment of the upper trapezius muscle, which is the most superficial posterior neck muscle.

Rectus Capitis Posterior Major

The rectus capitis posterior major muscle originates from a pointed tendon to the spinous process of the axis and attaches to the lateral part of the inferior nuchal line and the occipital bone immediately below it¹ (Figure 17-1). Interestingly, in the same study described above, Nayak et al² found two of these muscles on each side of a subject when the rectus capitis posterior minor muscles were absent. Scali et al,⁸ in an anatomic study, found a connective tissue bridge between the rectus capitis posterior major muscle and the cervical dura mater. The same authors conducted a histologic analysis of this connective tissue bridge between the rectus capitis posterior major muscle and the cervical dura

observing proprioceptive and neural afferences in this tissue.⁹

Obliquus Capitis Superior

The obliquus capitis superior muscle originates from tendinous fibers in the upper surface of the transverse process of the atlas and attaches to the occipital bone between the superior and inferior nuchal lines, lateral to the semispinalis capitis muscle and overlapping the insertion of rectus capitis posterior major muscle¹ (Figure 17-1). A study by Pontell et al¹⁰ has recently reported that the obliquus capitis superior muscle also attaches to the cervical dura by a connective tissue bridge such as the rectus capitis posterior minor and major muscles do. In fact, although this muscle and each of the rectus capitis posterior major muscles is independently connected to the dura mater, the proximity of their myodural connections leads to the appearance of a single atlantoaxial (AA) myodural bridge that links both suboccipital muscles to the dura mater.¹⁰ Again, in a histologic study, the same authors observed that the connective tissue bridge of the obliquus capitis superior muscle also exhibited neuronal and proprioceptive afferences, similar to the connective tissue bridge of the rectus capitis posterior major muscle.¹¹ Interestingly, all these myodural connections have also been observed by magnetic resonance imaging.¹²

Obliquus Capitis Inferior

The obliquus capitis inferior muscle, the larger of the two oblique muscles, originates adjacent to the upper part of the lamina of the axis and attaches to the inferoposterior aspect of the transverse process of the atlas¹ (Figure 17-1). The greater occipital nerve can be compressed at the obliquus capitis inferior muscle, near the spinous process of the axis, because it passes in close proximity to this muscle.¹³ In a small percentage of subjects this nerve travels through the muscle.¹⁴⁻¹⁶

Suboccipital Triangle

The suboccipital triangle is formed by the rectus capitis posterior major, the obliquus capitis superior, and the obliquus capitis inferior minor muscles. The triangular space is covered by the semispinalis capitis muscle and is filled largely with connective tissue. The posterior atlanto-occipital membrane and the posterior arch of the atlas form the floor of the triangle. The vertebral artery traverses the floor of this space in a groove on the surface of the posterior arch of the atlas. The greater occipital nerve crosses the ceiling of the suboccipital triangle.

2.1. Innervation and Vascularization

The suboccipital muscles are innervated by the branches of the dorsal primary division of the suboccipital (C1) nerve.¹ The C1 dorsal ramus passes dorsally and laterally through the suboccipital plexus of veins to enter the suboccipital triangle where it divides to form a

branch for the rectus capitis posterior minor muscles.¹⁷ One study showed that the dorsal rootlets of C1 had connections with the spinal accessory nerve 50% of the time.¹⁸ The suboccipital muscles receive their blood supply from the vertebral artery and deep descending branches of the occipital artery.¹

2.2. Function

The atlanto-occipital (C0-C1) and the AA (C1-C2) joints comprise the upper cervical region, which is the most mobile region within the entire vertebral column. These highly specialized joints facilitate precise positioning of the head and are involved in vision, hearing, smell, and equilibrium due to the function of the suboccipital muscles. Although the muscles do help to move the head on the neck, the main function of all suboccipital muscles is dynamic stability of upper cervical spine and proprioceptive feedback to the central nervous system.¹⁹ The fact that the suboccipital muscles have a higher density of muscle spindles confirms their role in proprioception.²⁰

Bilateral contraction of rectus capitis posterior minor and major muscles has been reported to contribute to the extension of the upper cervical spine, whereas a unilateral contraction of these two muscles contributes to ipsilateral rotation of the head.^{1,2} Although both rectus capitis posterior muscles can be functionally classified as extensor muscles, due to their small size, these muscles are better suited for small movements of the head on the neck and to control cervical lordosis.²¹ Their larger counterparts are better suited for the primary movement of the head and neck into extension.²² The obliquus capitis superior muscle seems to have the best leverage to assist with side-bending (Figure 17-2); however, this muscle is likely more important for posture.¹ The obliquus capitis inferior muscle is the only one primarily active during upper cervical rotation of the atlas on the axis, helping to rotate the face to the ipsilateral side.¹ Figure 17-2 graphs the orientation of the suboccipital musculature and summarizes the action of each muscle. Independent of their theoretical function, the main function of the suboccipital musculature is to contribute significantly to the maintenance of a normal, neutral head posture as well as dynamic stability of the head during the performance of daily activities that require extension, rotation, and side-bending of the head on the neck.

Figure 17-2. Graphic summary of the actions of the right suboccipital muscles.

In addition to these movements of the upper cervical spine, the head can also translate forward (protraction) and backward (retraction) within the sagittal plane. Typically, protraction of the head flexes the mid-lower cervical spine (C3-C7) and simultaneously extends the upper cervical spine (C0-C2). Retraction of the head, in contrast, extends or straightens the mid-lower cervical spine and simultaneously flexes the upper cervical region. Some recent studies have demonstrated that voluntary head retraction results in increased electromyographic activity in the rectus capitis posterior minor²³ and major²⁴ muscles. These studies concluded that head retraction results in eccentric contraction of both rectus capitis posterior muscles.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 17-1 grossly represents the functional unit of the suboccipital muscles.²⁵

Box 17-1 Functional unit of the suboccipital muscles

Action	Synergists	Antagonist
Upper cervical spine extension	Splenius capitis (bilaterally) Semispinalis capitis (bilaterally) Upper trapezius (bilaterally)	Longus capitis Rectus capitis anterior
Head rotation	Ipsilateral splenius capitis Contralateral sternocleidomastoid	Contralateral suboccipitals Contralateral splenius capitis Ipsilateral sternocleidomastoid

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in these muscles commonly refer pain unilaterally from the occiput to the temporal region, eye, and the forehead (Figure 17-3). The pain seems to penetrate inside the skull and is difficult to localize; however, it does not have the straight-through-the-head quality of pain like what is referred by the splenius cervicis muscle. Trigger points in the suboccipital muscles are clearly associated with tension-type headache,²⁶ but they have also been found in patients with whiplash-associated disorders,²⁷ fibromyalgia syndrome,²⁸ and migraine.²⁹

Figure 17-3. Referred pain pattern (dark red) of trigger points (TrPs) in the right suboccipital muscles (medium red).

3.2. Symptoms

Patients with TrPs in the suboccipital muscles report headache (either tension-type headache [TTH] or migraine) or neck pain. In addition, patients with cervicogenic headache can also exhibit TrPs in these muscles. They are likely to describe the headache as pressing, hurting “all over,” or more frequently like an eye mask.

When resting the head on a pillow in a supine position, patients often report a distressing headache that is of immediate onset. This pain is due to the weight of the occiput pressing against the pillow. Pain from the suboccipital muscles tends to be more deeply seated in the upper neck region and located more laterally than that experienced from the posterior cervical muscles. Patients often press with their fingers at the base of the skull, locating “a sore spot right here.”

Because the greater occipital nerve passes close to the obliquus inferior capitis muscle, it is possible that patients with occipital neuralgia may also exhibit TrPs in the suboccipital muscles. Patients reporting pain radiating unilaterally from the occipital bone to the eye should be carefully examined for tenderness in the greater occipital nerve.

3.3. Patient Examination

After a thorough, subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve and/or change. For a proper assessment and examination related to the suboccipital muscles, the clinician should assess posture, accessory motion of the C0-C1 and C1-C2 vertebral segments, and breathing patterns.

Individuals with headache and suboccipital muscle TrPs usually exhibit a forward head posture and restricted range of motion.³⁰ In fact, forward head posture is one of the most common cervical posture abnormalities observed in clinical settings. Because a forward head posture includes extension of the upper cervical spine segments, this position induces a compression of the cranio-cervical structures, particularly the suboccipital and posterior neck musculature. Visual assessment is the most common way to assess the posture of an individual. Griegel-Morris et al³¹ found a good intraexaminer ($\kappa = 0.825$) and a moderate interexaminer ($\kappa = 0.611$) reliability for postural visual assessment. Others have shown that the ability to detect a forward head posture is good as long as the differences are not subtle.^{32, 33} Other assessments such as photographs can be used for assessing a forward head posture in clinical practice³⁰ and have been shown to be reliable.^{34, 35}

In addition to head posture, suboccipital TrPs may also be related to the presence of upper cervical spine joint dysfunctions, particularly OA or AA joints. These areas need to be clinically examined and treated, if considered to be a source of symptoms or a contributing factor to the patient's reports. In fact, suboccipital tightness due to TrPs can limit upper cervical flexion. This should be carefully assessed (Figure 17-4A). Upper cervical spine flexion combined with side-bending can help diagnose unilateral dysfunctions

(Figure 17-4B). For specific details regarding the evaluation of upper cervical spine dysfunctions, refer to other texts on this topic.

Figure 17-4. Tests for restricted motion due to tight suboccipital muscles. A, Restricted movement of the head on neck is found by flexing the atlanto-occipital joint (O-C1) and noting early motion between C2 and C3. B, Testing combined flexion of the atlanto-occipital joint (O-C1) with side-bending of the head on neck.

Several studies have demonstrated that a manual assessment of upper cervical spine dysfunctions can help to diagnose patients with headache of cervical origin properly.^{36,37} Proper manual assessment assists in the differential diagnosis between suboccipital muscle TrPs and upper cervical joint dysfunctions. In fact, both impairments can contribute to upper cervical joint restrictions. For instance, the cervical flexion–rotation test has been proposed as a proper tool for the diagnosis of upper cervical joint restriction. The cervical flexion–rotation test is conducted by placing the patient’s neck in full flexion while passively rotating the head to one side (Figure 17-5A and B). The basis of the test is that cervical motion is more isolated to the C1-C2 (AA) level when the cervical spine is held in full flexion. It has been found that patients with cervicogenic headache have an average of 25° to 28° of AA rotation to the side of the headache as compared with an average rotation of 44° toward the asymptomatic side and as compared with healthy people (difference: 10°-15°). The cervical flexion–rotation test showed an overall diagnostic accuracy of 85% to 91%.³⁸ Frequently, a restriction in rotation toward one side is due to shortened suboccipital muscles, particularly the contralateral obliquus capitis inferior muscle. An alternative test for the AA joint is performed by placing the patient’s neck in full lateral flexion while passively rotating the head to the opposite side (Figure 17-5C and D). Crepitus is a very common finding in patients with osteoarthritis of this joint.³⁹ In these patients, pain is often due to suboccipital TrPs.

Figure 17-5. A and B, Cervical flexion–rotation test for isolated testing of the C1-C2 (AA) joint (left rotation) and right suboccipital muscle length. C and D, Cervical lateral flexion with contralateral rotation for isolated testing of the C1-C2 (AA) joint and right suboccipital muscle length. The same position can be used for treatment utilizing postisometric relaxation techniques.

3.4. Trigger Point Examination

Suboccipital muscles are the most deeply placed muscles just below the base of the skull. This region is also one of the most sensitive and tender areas of the body to palpate; thus, clinicians should be cognizant of the amount of pressure used with palpation in this area. These muscles are not directly palpable because the upper trapezius and other posterior neck muscles are more superficial. The application of pressure on the anatomic projection of each muscle, however, is able to elicit the referred pain from these muscles, which is clearly different from that of splenius capitis or upper trapezius muscles. It is seen in clinical practice that palpation of each of the suboccipital muscles, in some patients, can elicit slightly different referred pain patterns than that reported by Simons et al.²⁵ Fernández de las Peñas et al²⁶ developed a protocol for the diagnosis of TrPs in the suboccipital muscles. Although this has not been validated. It includes tenderness in the suboccipital area, referred pain elicited by maintained pressure, and increased referred pain on muscle contraction, specifically extension of the upper cervical spine.

Rectus Capitis Posterior Minor

The rectus capitis posterior minor muscle is located between the posterior tubercle of atlas (C1) and the occiput,⁴⁰ 1 cm lateral to the midline. For identification of its anatomic projection, the clinician starts palpating just superolateral to the posterior tubercle of C1. Another anatomic reference is the ligamentum nuchae. Utilizing cross-fiber flat palpation, the clinician should first locate the rectus capitis posterior minor region through the more superficial cervical muscles, then move toward the occipital attachment.

Rectus Capitis Posterior Major

The rectus capitis posterior major muscle is located between the spinous process of the axis (C2) and the occiput, just lateral to the rectus capitis posterior minor muscle.⁴⁰ For identification of its anatomic projection, the clinician starts palpating just to the spinous process of the axis. Cross-fiber flat palpation is utilized to locate the rectus capitis posterior major region through the more superficial muscles, continuing with assessment in the direction of the occipital attachment.

Obliquus Capitis Superior

The obliquus capitis superior muscle is located between the transverse process of the atlas (C1) and the occiput, just lateral to the superior attachment of the rectus capitis posterior major muscle.⁴⁰ This muscle is very challenging to palpate and to discern from superficial posterior neck musculature. The clinician should palpate starting on the occipital attachments, just lateral to the rectus capitis posterior major muscle and medial from the mastoid process. Cross-fiber flat palpation is utilized to locate the obliquus capitis superior region through the more superficial cervical muscles and continuing with assessment toward its lower attachment.

Obliquus Capitis Inferior

The obliquus capitis inferior muscle is located between the spinous process of C2 and the transverse process of C1, deep to the splenius capitis muscle.⁴⁰ Between these landmarks, the clinician palpates through the more superficial cervical muscles with a cross-fiber flat palpation technique to identify the obliquus capitis inferior region. The fiber direction of this muscle is typically more horizontal than what is depicted in anatomic pictures.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any portion of the suboccipital muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or sub-maximal concentric loading.⁴¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. Because the

suboccipital muscles are largely responsible for moving the head on top of the neck, they are likely to develop TrPs when working at either extreme range of motion. The checkrein function of the suboccipital extensors is overloaded by sustained forward flexion of the head and neck, which often occurs while using handheld electronic devices. If a person tips the head upward, the suboccipital musculature is strained by prolonged contraction (eg, when a person lies prone on the floor, propped up on the elbows to support the head while watching television).

Excessive forward head posture is usually accompanied by the extension of the upper cervical spine to accommodate for the line of vision, such as with excessive computer use. This position activates and perpetuates TrPs in the suboccipital muscles and other posterior cervical muscles. Mouth breathing as compared with nasal breathing has also been shown to have a negative impact on posture.⁴²⁻⁴⁷

Patients who are intensely preoccupied with desk or computer work are susceptible to losing track of time in an undesirable posture. In other muscles, TrPs have been shown to develop with 1 hour of typing, with visual and postural stressors,⁴⁸ and are plausible for these muscles as well.

Maladjusted eyeglass frames, uncorrected nearsightedness, lenses with too short a focal length, and the use of progressive lenses that require frequent or sustained fine adjustment of the head position can also activate and perpetuate TrPs in these muscles.

The rotation and head-tilt functions may be overused by sustained off-center head positions, as when the subject is talking to someone who is off to one side, sight-seeing to only one side from a vehicle, avoiding the glare from a strong light source that reflects off the inside of the eyeglass lenses, or by prolonged attention to work placed flat on the desk to the side of the keyboard.

Chilling the back of the neck, while tired neck muscles are being held in a fixed position, contributes to the activation of TrPs in these muscles.

Finally, any traumatic event with an impact on the cervical spine or the head, for example a whiplash injury, can activate TrPs in these muscles. Research supports the association of TrPs in other muscles and whiplash,^{49,50} thus it is plausible that TrPs can develop in the suboccipitals as well. Patients with a whiplash injury are known to develop refractory head and neck pain symptoms, probably due to joint injury and TrPs.⁵¹ Unfortunately these patients are rarely examined properly and treated for the part of their pain that is of a muscular origin.

4.2. Associated Trigger Points

Trigger points rarely appear in the suboccipital musculature alone; commonly those with a headache will have TrPs in the upper trapezius, temporalis, and semispinalis capitis muscles. They are also likely to be associated TrPs in the other masticatory muscles.

The referred pain from suboccipital TrPs may appear similar to, or overlap, the patterns of the temporalis, upper trapezius, sternocleidomastoid, splenius cervicis, and semispinalis capitis muscles; therefore, a thorough examination of each of these muscles is necessary.

Trigger points can also develop in the referred pain areas of TrPs,⁵² therefore TrPs in the suboccipital muscles can be due to primary TrPs in other muscles including the upper trapezius, lower trapezius, splenius cervicis, and cervical multifidi muscles. Primary TrPs can also contribute to associated TrPs in other muscles including the occipitofrontalis, temporalis, orbicularis oculi, and corrugator muscles.

4.3. Associated Pathology

Patients with suboccipital TrPs are commonly diagnosed as having tension-type headache,⁵³ cervicogenic headache,⁵⁴ occipital neuralgia,⁵⁵ or chronic intractable benign pain. Chronic intractable benign pain is defined as “non-neoplastic pain of greater than 6 months duration without objective physical findings and known nociceptive peripheral input.”⁵⁶ One study of patients with the “diagnosis” of chronic intractable benign pain of the neck reported TrPs or tender points in suboccipital muscles in 67.6% of 34 patients.⁵⁶ It is possible that patients with this diagnosis are today considered as suffering central sensitivity syndromes.⁵⁷

Dural headache should be considered in the differential diagnosis of patients because of unique anatomic considerations with these muscles.⁵⁸ As Hack and Hallgren stated “The presence of a connective tissue bridge, attaching suboccipital muscles to the dura mater, is now recognized as a feature of normal human anatomy. The role that this myodural bridge may play in headache production is uncertain; however, a new conceptual model is emerging. Postsurgical myodural adhesions have been reported as a complication resulting from excision of acoustic tumors. Extensive research now exists implicating these myodural adhesions as a possible source of postoperative headache.”⁵⁹ The authors report a case study of a single patient who experienced relief from chronic headache after a surgical procedure was performed to separate the suboccipital myodural bridge. Given this understanding of the connection between the suboccipital muscles to the dura, patients dealing with headache symptoms should be properly diagnosed before suboccipital TrP treatment is started. For instance, when a patient presents to the clinic with head pain but has not been previously examined by a physician, a thorough examination and medical screening should be conducted to rule out other underlying medical conditions. If warranted, referral to an appropriate medical practitioner for further diagnostic workup should be done.

Some studies have demonstrated that the suboccipital musculature, particularly the rectus capitis posterior minor and major muscles, exhibits larger amounts of fatty infiltrate in patients with whiplash-associated disorders⁶⁰ and decreased cross-sectional area in women with chronic tension-type headache.⁶¹ Whether these muscle changes are a primary or secondary phenomenon remains unclear. In any case, fatty infiltration in these muscles could be associated with several mechanisms including generalized disuse, chronic denervation, motor-neuron lesions, metabolic disorders, or other muscle impairments.⁶⁰ Atrophy could possibly account for a reduction of proprioceptive output from the suboccipital musculature and thus contribute to the perpetuation of TrPs.^{61, 62}

Nerve entrapment has not been clinically observed as resulting from TrPs in the

suboccipital muscles; however, TrPs in the obliquus capitis inferior muscle could potentially be a source of entrapment for the greater occipital nerve because this nerve has been shown in some instances to pierce the muscle.^{14–16}

5. CORRECTIVE ACTIONS

For patients who develop TrPs in the suboccipital muscles, it is important to keep this part of the neck warm by wearing a turtleneck or a hood that covers the head and neck outdoors. Sleepwear rarely provides a collar high enough to cover the suboccipital area adequately; therefore, the patient should wear a soft hooded jacket or drape a scarf or bed covers in such a way as to keep the suboccipital region warm.

Sustained upward gaze, with the head tilted up, should be avoided for any activity by modifying or eliminating that activity. In a case seen by Dr Travell,²⁵ a stage director learned to direct the performance from farther back in the theater instead of from the front row where he had been at a level lower than that of the actors on the stage. This change allowed him to face the actors without looking up for prolonged periods.

Forward head posture and tongue position should always be corrected when identified as a problem. Instruction in good body mechanics is also essential (refer to Chapter 76).

To maximize the benefits of postural training, patients should be trained in naso-diaphragmatic breathing instead of mouth breathing, as mouth breathing has a negative impact on posture.^{42–47} Performing strengthening exercises on a Swiss ball and stretches in conjunction with naso-diaphragmatic breathing has been shown to improve the posture⁴⁶ and decrease the activity of the suboccipital muscles.^{46, 63}

Sustained and strained positions of the head are reduced by (1) avoiding the use of trifocals; (2) using lenses with adequate focal length for the task at hand to allow the head to rest in a balanced upright position on top of the cervical spine; (3) rearranging the location of the patient or the room lighting to eliminate glare reflected from the inside of the lenses (or using antiglare lenses); (4) placing documents on a vertical stand; and (5) avoiding prolonged use of handheld electronic devices in the lap for lengthy tasks. Additional postural considerations are included in Chapter 76.

Intense preoccupation during desk tasks can result in a patient maintaining an undesirable posture for prolonged periods. Because TrPs have been shown to develop within 1 hour of typing,⁴⁸ desk workers should relieve muscle tension every 20 to 30 minutes by setting an interval-timer to remind them to take small breaks.

The rectus capitis posterior minor and major muscles can exhibit atrophy and fatty infiltration^{60, 62, 64, 65} similar to the posterior cervical muscles after whiplash^{66, 67} and therefore should be strengthened appropriately. Some recent studies have demonstrated that voluntary head retraction results in increased activity in the rectus capitis posterior minor²³ and major²⁴ muscles by inducing an eccentric contraction of both the muscles (Figure 17-6). Refer to supplementary texts on exercise prescription for more information.⁶⁸

Figure 17-6. Active neck retraction from a neutral head position. A and B, In a seated or standing position, the patient actively retracts the head to bring the chin in line while the eyes stay level with the horizon. There should be no tipping of the head in a forward or backward direction.

Finally, patients should learn how to relax the neck muscles and how to perform a passive self-stretch while seated on a stool or chair and, if possible, under a warm shower. The patient performs this stretch by manually assisting a nodding motion (flexion of the head on the neck) with the patient's fingers under the occiput (Figure 17-7). The patient uses his own fingers under the occiput to exert upward traction prior to directing the movement of the head. A comparable self-stretch for the suboccipital muscles is described and illustrated by Lewit.⁶⁹ A series of passive stretches should be applied separately in unidirectional movements (no head rolling) with successive degrees of head rotation to fully stretch all the suboccipital muscles. Passive stretching should be followed by full active range of motion, contracting and stretching both agonists and antagonist muscles. This cycle of movements is repeated 3 to 5 times every couple of hours, slowly and without jerking.

Figure 17-7. Self-stretching exercises of the suboccipital musculature. Stretch of the rectus capitis posterior major, minor, and obliquus capitis superior muscles. A and B, The patient flexes the head (by tucking the chin toward the chest) and nods the head forward.

Clinical Considerations of Head and Neck Pain

César Fernández de las Peñas and María Palacios-Ceña

1. INTRODUCTION

Myofascial pain resulting from trigger points (TrPs) usually refers symptoms to both muscular and nonmuscular structures. In the head and neck regions, the patient may report having facial pain, headache, toothache, sinus pain, or temporomandibular joint (TMJ) pain. Clinical evaluation of these areas may not yield any evidence of local pathologic change. In fact, any undiagnosed pain, particularly but not exclusively deep, dull, and aching in character, may be of myofascial origin. If a patient describes two components to the pain or notes a dull aching quality in addition to other pain descriptors, pain from TrPs should be suspected as a contributing factor. The intensity of myofascial pain due to TrPs should not be underestimated because it has been rated by patients as equal to or greater than pain from other causes.¹ It is of paramount importance to distinguish between TrP origins and other pain syndromes in the head and neck.

1. TEMPOROMANDIBULAR DISORDER

1.1. Overview

Temporomandibular disorder (TMD) is a term including different conditions involving the TMJ, the masticatory muscles, and their associated tissues (eg, ligaments, disc, and connective tissues) that represent a clinical problem such as pain, limited jaw movements, and TMJ noises. There are several different TMDs; myofascial TMD and internal TMJ derangements are the most common subtypes. TMD pain is characterized by a classical triad of clinical features: muscle and/or joint pain; TMJ crepitus sounds, clicking, or popping (in the case of disc displacement or degenerative joint disorders); and restriction, limitation, or deviation of the mandible during mouth opening and closing movements.^{2,3}

The lifetime prevalence of TMD is unclear, but some studies have shown prevalence rates ranging between 3% and 15% in the Western population, and incidence rates ranging between 2% and 4%.⁴ Women are more frequently affected than men (ratio 2:1).⁵

Myofascial TMD is the most frequent diagnosis (42%), followed by disc displacement with reduction (32.1%), and arthralgia (30%).⁶

This condition, particularly myofascial TMD, is commonly comorbid with other entities (eg, headaches). Gonçalves et al⁷ found that subjects with myofascial TMD were significantly more likely to suffer from chronic daily headaches, migraine, and tension-type headache (TTH) than individuals without TMD pain.

One of the common clinical features of TMD includes spontaneous face pain or pain with mandibular motion. Patient-based drawings of their pain symptoms demonstrate a concentration around the masseter muscle and spreading to the temporalis muscle. The pain is felt deep and “spreading pain” is a descriptive phrase commonly used by patients. This presentation is a cardinal symptom in patients with a diagnosis of myofascial TMD pain, although not exclusive of this condition. The words describing the pain of patients suspected to have been dealing with myofascial TMD resemble the pain features of TrPs in general.

Another typical clinical sign of myofascial TMD is the tenderness or pain on palpation of muscle structures, particularly the masticatory musculature. Masticatory muscles are easily accessible to manual palpation and some authors have standardized the areas that should be explored as well as the pressure and time to be applied; however, no consensus has been achieved on this topic. Recommendations from the Diagnostic Criteria for TMD suggest 1 kg for 2 seconds to be applied to the masseter and temporalis muscles, and 0.5 kg to the TMJ.⁸

1.2. Initial Evaluation of Patients with Temporomandibular Disorder Pain

When a patient with TMD pain seeks treatment, a comprehensive initial evaluation is needed to determine if the patient would be a candidate for TrP management, referral to another professional (eg, Dentist), or a combination of treatment and referral. Clinicians should record the pain history including area and behavior, aggravating and alleviating features, and maneuvers or positions that increase or reduce symptoms. It is important that clinicians record and listen to the patient’s description of their symptoms. Symptom descriptors such as deep, widespread, diffuse, pressure, or tight would indicate the presence and importance of referred pain from TrPs. Box 18-1 summarizes some pain features that may assist clinicians in identifying which TrPs to look for.

Box 18-1 Pain features that assist the clinician with examination of relevant TrPs

The McGill Pain Questionnaire may be useful to assess the quality of pain symptoms. During the subjective examination or patient interview, the clinician should note the following pain descriptions that may suggest the presence of TrPs.

“It feels like my head or neck is burning.”

“My neck just feels so tight. My movement feels restricted.”

“It feels like a lot of pressure in my head, like it’s being compressed.”

“My head feels really heavy. I feel like it is hard to hold up.”

Regardless of the source of symptoms, a thorough examination and evaluation of the TMJ and cervical spine screening should be carried out. The examination should include examination for TrPs that may be the source or contributing factor of the patient's presentation. The following sections summarize some common clinical aspects of the TMJ examination.

Joint Capsule Tenderness

Pain emanating from the TMJ itself is almost always associated with inflammation of the joint capsule or retrodiscal tissues, which results in the sensitization of these structures. Palpation of the TMJs often reveals tenderness if an acute inflammatory process is present. Palpation of the lateral poles, which are located just anterior to the tragus of the ear symptoms, may reveal tenderness or reproduce the patient's symptoms, indicating joint capsule involvement.⁹ Firm palpation may be uncomfortable in healthy people but is only painful if the joint capsule is inflamed. Simultaneous palpation allows the patient to compare the sensations of one side to the other. Palpation of the lateral pole of the TMJ has shown fair to slight interrater agreement.^{10,11} Palpation of the posterosuperior part of the joint can be accomplished by placing a finger in each external auditory meatus; here, potentially inflamed retrodiscal tissues can be identified as a source of the patient's symptoms.

An interesting observation is the report of persistent periarticular TMJ pain in the absence of joint inflammation. In this case, any tenderness to joint palpation is relatively mild compared with typical presentation of an acute inflammatory condition. This persistent periarticular tenderness may arise from masseter, pterygoid, and/or sternocleidomastoid TrPs that result in referred pain to the joint with associated secondary cutaneous and deep tissue hypersensitivity.¹²

Presence of acute inflammatory TMJ pain is clearly a reason to refer the individual to a dentist trained in orofacial pain and TMD. Resolution of joint inflammation is certainly essential for resolution of any concurrent masticatory muscle TrPs. The pain from an acutely inflamed joint restricts any masticatory muscle stretching and TrPs recur secondary to the central excitatory effects from the nociceptive source. Palliative care is essential to achieve resolution of the inflammatory process. One can start to manage any TrPs, while instituting palliative joint care, by simultaneously educating the patient in the resting position of the jaw, good posture and body mechanics, and reducing or eliminating parafunctional oral habits such as gum chewing, fingernail biting, and pen chewing. Once the joint inflammation is under control, masticatory TrPs can be thoroughly addressed if still necessary. Once acute inflammatory conditions have been ruled out, the remaining tests help determine the extent of TMJ internal derangement if present.

Joint Clicking Sounds

Although many TMJ disorders are accompanied by some variation of joint sounds, there is no reproducibly reliable clinical test to examine for these.^{11,13} However, one study found that TMJ-related pain was correlated with TMJ-related magnetic resonance imaging diagnoses of internal derangement and osteoarthritis.¹⁴

Palpation involves placing the pad of the index fingers over each TMJ (just anterior to the tragus of the ear) while the patient opens and closes the mouth. A normal joint is essentially silent and moves smoothly. Crepitation (rough, sandy, or diffuse noise or vibration) is usually a sign of degenerative joint changes (eg, osteoarthritis). Discrete clicks and pops may represent a mechanical problem with the disc or more localized disc and articular surface abnormalities. The timing, quality, and intensity of joint noises help define the type and severity of joint involvement.¹⁵ A loud discrete click on opening, followed by a quieter, less-intense click on closing (called a reciprocal click) is typical of an anteriorly displaced disc with reduction. The location of the opening click is usually at wider jaw opening than the closing click which often occurs just before the teeth come together. Discrete clicks that occur at the same point on opening and closing probably represent discrete disc and articular surface abnormalities. Not all intra-articular interferences with joint movement result in noise. Occasionally, only a brief lateral shift in the mandible or condyle is evident on examination. The presence of joint sounds alone, however, does not mean that the patient has a TMD. Many people have joint sounds without any sign of true joint disease.^{15,16} Readers are referred to other texts for further info on TMJ examination.^{3,17}

Auscultation using a stethoscope placed lightly over each TMJ while the patient opens and closes may be used to amplify joint sounds for clinical purposes. The technique is only moderately reliable (50%-65% agreement) when used by trained examiners, even when they were using a split stethoscope with two earpieces and one diaphragm.¹⁸ Another study reported that the interexaminer reliability was moderate ($\kappa = 0.47-0.59$) for tests recording joint sounds.¹⁹ Other studies have even less reliability when listening for joint sounds.¹¹

Because the mandible connects the two TMJs, transfer of vibration and sound often makes it difficult to assess which joint, if only one, is causing the noise or irregular movement. Sometimes, the patient clearly senses which joint is involved; if not, another method involves continuing to palpate the lateral poles of the joints while the patient moves his or her jaw to the left and to the right without opening more than 1 or 2 mm. Although it is generally accepted that an involved right joint clicks or crepitates with jaw movements to the left and vice versa, this method of examination showed unacceptable between-examiner agreement for research purposes when studied.¹⁵ Readers are referred to other texts for further info on TMJ examination.^{3,17}

The presence of internal derangements is not a contraindication for treatment of TrPs. In fact, there is a widely accepted clinical opinion that the lateral pterygoid muscle may be dysfunctional in patients with TMD. The theory of internal derangement of the TMJ involves the anterior displacement of the disc as result of hyperactivity of the lateral pterygoid muscle. This hypothesis is based on the attachment of the superior head of the

lateral pterygoid muscle which may pull the disc in an anterior and superomedial direction.²⁰

Mandible Range of Motion

The mandible movements usually assessed in clinical practice include a maximum opening (passive/active), maximum bilateral excursions, and a maximum protrusion. However, restricted mandible movements do not provide relevant information for any specific diagnosis since multiple factors can be related to this impairment.

The normal minimum interincisal range of jaw opening is generally accepted to be between 36 and 44 mm with a maximum normal range of motion (ROM) of up to 60 mm. A quick screening test for normal jaw opening involves asking the patient whether he or she can fit the first two knuckles of the nondominant hand between the incisor teeth. In the absence of internal derangement and TrPs, all healthy people can accomplish this and some can fit three knuckles. For a reproducible numerical value, interincisal opening should be measured with a sterilized or linear disposable millimeter ruler. It is useful to use a ruler where zero is directly at one end of the ruler without any indentation space. Place the “0” end on top of one of the lower central incisors and measure to the incisal edge of the corresponding upper central incisor. The assessment should always be conducted between the same central incisors to be able to compare measurements from one time to the next. This is a very reliable and reproducible clinical measure and “represents the gold standard for evaluating mandible movement.”^{10,21,22} Readers are referred to other texts for further info on TMJ examination and assessment.^{3,17}

Clinically, three vertical mandible measurements are useful: maximum comfortable opening, full unassisted opening (active ROM), and assisted opening (active assisted ROM). The pain-free ROM should be at least 36 to 44 mm. A normal joint has 1 to 2 mm of “give” at end range with manual assistance from the clinician. Restriction of oral opening due to muscle splinting may result in a relatively dramatic increase in jaw opening with the assisted range testing maneuver, although the patient may complain of pain. Muscular restriction may also cause tremor and reflex muscle guarding against the opening pressure. Restriction of the oral opening due to mechanical obstruction or ankylosis in the TMJ typically results in a hard end feel and no increased range.

Hypermobility of the TMJ (jaw opening greater than 60 mm) and history of open dislocations are indications for caution with assisted stretch of the masticatory muscles. This presentation contrasts starkly to one of restricted mouth opening which indicates internal derangement or ankylosis of the TMJs, tightness of the joint capsule, restriction due to muscular splinting, TrPs, or a combination of these factors. The mandible midline tends to deviate toward the side affected with the most pronounced joint and/or muscle restriction.

In general, restricted mandible ROM is an indication to institute jaw exercises and muscle treatment. Contraindications to opening exercises are limited and include:

1. True acute arthralgia, usually due to some inflammatory process, is a contraindication to muscle stretching due to pain and reflex muscle splinting. Once this has resolved, muscular stretching is permissible as needed.
2. Painful internal derangement.
3. Significant history of locking (frequent episodes of inability to open the mouth without any manipulation first).

If a patient exhibits a limited range of mandible motion and little is gained by muscle therapy, the TMJ capsule may be tight. Skilled joint mobilization would be the treatment of choice to improve mouth opening.²³ There are ample resources available to clinicians to learn these techniques.²⁴

Mandible Path of Opening and Closing

The clinician should observe the path of mouth opening and closing, looking for S or C deviations from a straight path; these may be indicative of mechanical problems within the joint or muscle imbalances.

The jaw tends to deflect toward the side affected with an internal joint derangement or restricting mobility of the individual joint or to the side with masticatory muscle shortening or TrPs. Trigger points in the masseter or temporalis muscle can deviate the jaw to the same side, whereas TrPs in the medial or lateral pterygoid muscle deviate the jaw to the opposite side. The presence of jaw aberrant motion alone, in absence of inflammation or painful internal derangement, is not a contraindication for the treatment of TrPs. However, a significantly restricted mandible ROM (<36 mm) along with deviation to one side and a hard end feel may be indicative of either unilateral ankylosis or an anteriorly displaced disc without reduction. This joint situation merits an evaluation by a specialist in TMD although basic TrP pain management strategies such as specific TrP therapy, resting position of the jaw, good posture, and good body mechanics can be instituted immediately.

1.3. Trigger points and Temporomandibular Disorders

TMD diagnosis is mainly based on a combination of defined signs and symptoms. The most accepted worldwide diagnostic criteria are the Research Diagnostic Criteria for TMD, proposed in 1992²⁵ and currently being replaced by the validated Diagnostic Criteria for TMD (DC TMD).⁸ Within the Research Diagnostic Criteria for TMD, axis I and axis II are mainly included. Three major diagnostic categories contemplated in axis I are myofascial pain, disc alterations, and arthralgia–arthritis–arthrosis.²⁵ Axis II contemplates the psychological aspects of TMD pain by including specific questionnaires assessing depression and anxiety, among other features.²⁵ The DC/TMD uses the same double-axes approach with three major groups related to axis I: muscle pain, TMJ disorders, and headache attributed to TMD.⁸

The term myofascial TMD clearly suggests that TrPs play a relevant role in the genesis of the pain. Of course, the most important part of any diagnostic effort is obtaining a good

history; this is often enough to make a fairly accurate preliminary determination of the probable cause. Once it is clear that the patient may be suffering from either an articular disorder, TrPs, or a combination of both, the following examination techniques help delineate the extent of TMJ involvement. In clinical practice, it is highly common to see a combination of both muscle and joint imbalances independently of the main diagnosis.

Painless joint disorders are not typically associated with the development of TrPs. It is the acute, painful inflammatory process that may intermittently or persistently accompany chronic joint conditions that tend to herald the onset of TrPs. Acute inflammation intrinsic to the joint or acute stages of arthritis are the usual causes of pain emanating from the joint itself. In an older study conducted at the University of Minnesota TMJ and Facial Pain Clinic, doctors evaluated 296 consecutive patients with chronic head and neck pain complaints.²⁶ Only 21% of these patients had a TMD as the primary cause of pain. In all the 21% patients, the joint disorder included an inflammation of the TMJ capsule or the retrodiscal tissues. This type of pain is characteristically periarticular and aching in quality and will respond to acute pain management therapies; however, because these disorders are almost always accompanied by reflex muscle splinting, spasm, or pain, it is common to see the development of TrPs especially if the inflammation is prolonged or recurrent. Pain due to TrPs was the primary diagnosis in 55.4% of the patients in the Minnesota study, almost three times the incidence of primary joint pain. Painless internal derangements of the TMJs were felt to be a perpetuating factor of TrPs in 30.4% of the patients.²⁶ Therefore, it is important to make a distinction between true TMJ pain, pain due to TrPs alone, and pain due to TrPs that is being perpetuated by a noninflammatory or intermittently inflammatory joint condition. Treatment priorities are affected accordingly.

Scientific data from human pain models clearly support the notion that referred pain from masticatory muscles may be involved in myofascial TMD pain.²⁷ Nevertheless, clinical evidence is scarce. A nonblinded study revealed that the referred pain patterns following a manual stimulation of TrPs in the masticatory muscle was similar to the pain pattern experienced by individuals with TMD.²⁸ A blinded controlled study²⁹ demonstrated the existence of multiple active TrPs in the masticatory and neck–shoulder musculature in women with myofascial TMD. In this study, both local and referred pain elicited from manual palpation of active TrPs reproduced the pattern of pain symptoms in all TMD patients. It is suggested that different muscles may be involved in TMD and TTH. TMD pain is clinically more similar to the pain patterns produced by stimulation of the masseter muscle; in contrast, TTH is more similar to the pain patterns evoked by stimulation of cervical muscles, for example, upper trapezius.³⁰

2. NECK PAIN SYNDROMES AND HEADACHES

2.1. Overview

Since headaches constitute a serious health problem, there has been an increasing interest in the pathogenic mechanisms of these pain disorders.³¹ Among all the described headaches, attention from clinicians has focused on those three most prevalent: TTH, cervicogenic

headache, and migraine. Population-based studies suggest a 1-year prevalence rate of 38.3% for the episodic form of TTH, and 2.2% for the chronic form,³² making it the most common headache form. A more recent study reported that in the 21st century 42% of the patients suffer from TTH.³³ Although TTH is one of the most common headaches, it is also the most neglected.³⁴ Nillson reported the prevalence of approximately 16% of cervicogenic headache in a Scandinavian population.³⁵ The accepted prevalence for cervicogenic headache, using clinical criteria for the diagnosis, ranges from 1% to 4.1% of the general population.³⁶ Finally, an older population-based study estimated that 10% to 12% of adults have experienced migraine in the previous year making it the third most common.³⁷ More recent studies reported that the average lifetime prevalence of migraine seems to be 18% whereas the estimated average 1-year prevalence is around 13%.^{38,39} A recent study observed that the prevalence of migraine increased in the first decade of the 21st century in Spain.⁴⁰

Functional and work disability has been described by 60% of patients with headache and accounted for 64% of the reduction in working capacity due to head pain.⁴¹ Importantly, quality of life is reduced by headache.^{42,43} Recently, the Global Burden of Disease ranked migraine as the eighth most burdensome disease and as the first among neurologic conditions.⁴⁴

Tension-Type Headache

Tension-type headache is characterized by attacks lasting from 30 minutes to 7 days with at least two of the following features: (a) bilateral location, (b) pressing and tightening pain quality, (c) mild or moderate pain intensity, and (d) lack of aggravation during routine physical activity. In addition, patients should not report photophobia, phonophobia, vomiting, or evident nausea during headache, although one of these features is sometimes permitted. Different versions of diagnostic criteria for headaches have been published in the last few decades by the International Headache Society^{45,46} and more recently published in 2013.⁴⁷ No significant changes in the diagnostic criteria of TTH have been included.

Cervicogenic Headache

Cervicogenic headache is mainly characterized by the following: (a) generalized unilateral pain, (b) moderate to severe pain intensity, (c) nonthrobbing or nonlancinating pain quality, and (d) restriction of the range of neck motion. The required criteria for the diagnosis of this condition include head pain increased by head movement, maintained neck postures, or external pressure over the upper cervical joints.⁴⁸ Diagnostic criteria of this type of headache have been revised and modified in the third edition of the International Classification of the Headache Disorders (ICHD) (11.2. Headache attributed to disorders of the neck to 11.2.1 Cervicogenic headache).⁴⁷ There is a significant controversy regarding whether the signs and symptoms of neck involvement represent a true cervical source for head pain.

Migraine Headache Without Aura

Migraine headache without aura is characterized by attacks lasting from 4 to 72 hours with at least two of the following features: (a) unilateral location, (b) pulsating pain quality, (c) moderate or severe pain intensity, and (d) aggravation by routine activities. Furthermore, migraine attacks should be associated with phonophobia or photophobia.⁴⁷

While some patients may present with two types of headaches simultaneously (TTH with migraine features, cervicogenic headache with TTH characteristics, etc.), it seems that the pain quality and features of these headaches are different. Differences in pain features may implicate different structures responsible for nociceptive irritation of the trigeminocervical nucleus caudalis.⁴⁹ For instance, pain features of cervicogenic headache suggest a peripheral nociceptive mechanism, for example, muscle or joint etiologic role of the pain; in contrast, pain features of migraine suggest the activation of the trigeminovascular system.^{50,51} Nevertheless, from a theoretical and clinical viewpoint, muscle referred pain evoked by TrPs can contribute to pain perception in these headaches. Headaches that involve a significant component of pain referred from TrPs have been called myogenic headaches to indicate the role of muscle in the genesis of the headache.^{52,53} Because nociceptive somatic afferents from muscles innervated by upper cervical roots (particularly C1-C3) and the trigeminal nerve (particularly V1 or ophthalmic and V3 or mandibular nerves) converge on the same relay second-order neurons (trigeminocervical nucleus caudalis), it is understandable that TrPs located in any head, neck, or shoulder muscle could refer pain to the head and contribute to pain perception in these headache disorders.

The pain features of TTH, cervicogenic headache, and migraine without aura resemble the descriptions of referred pain (steady, deep, aching pain) originating in TrPs. Because TrPs and other structures such as upper cervical joints or nerve tissues can contribute to head pain perception at the same time, clinicians should focus the differential diagnostic process on pain history, pain features, and pain provoking or relieving maneuvers to identify which TrPs are causing the patient's headache or neck pain complaint.

Several studies have reported increased tenderness to muscle palpation in patients with TTH or cervicogenic headache without identifying the presence of TrPs.⁵⁴⁻⁵⁶ In addition, lower pressure pain thresholds (PPT) have been observed in both cephalic (eg, temporalis region) and extracephalic (eg, upper trapezius) regions when compared with healthy subjects.⁵⁷⁻⁵⁹ However, latent TrPs constitute a different clinical entity than active TrPs. It has not been until the last decade that multiple studies have investigated the role of TrPs in head pain syndromes and even more recently that TrP studies distinguish active and latent TrPs. An exception is a study published more than three decades ago that demonstrated the role of pain referred from TrPs in the neck and shoulder muscles to the head, relevant to the pain of headache, and demonstrated that treatment of the TrPs by injection relieved the headache.⁵²

It is also common that patients with headache have referred symptoms to and from the cervical spine. A recent study found a prevalence of neck pain of 89.3% in patients with

migraine combined with TTH, 88.4% in those with TTH, and 76.2 in those with migraine.⁶⁰

Neck Pain

Neck pain affects 45% to 54% of the general population at some time during their lives.⁶¹ The lifetime prevalence of neck pain has been estimated to be between 67% and 71% indicating that approximately two-thirds of the general population experiences an episode of neck pain at some time during their life.⁶² Neck pain can be classified as idiopathic or mechanical neck pain or neck pain associated with a rear-end motor vehicle accident (whiplash-associated disorders, WAD). Mechanical or idiopathic neck pain can be defined as generalized neck and/or shoulder pain with mechanical characteristics including symptoms provoked by awkward neck postures or movement or by palpation of the cervical muscles. Pain often has a gradual onset, without a clear cause for its origin. The pain profile in neck pain syndromes can be related to different anatomic structures: zygapophyseal joints, neural tissues, discs, muscles, or ligaments.⁶³ Nevertheless, in clinical practice it seems that TrPs are one of the main causes for neck pain symptoms.

Neck and head pain are common clinical manifestations of whiplash injuries.⁶⁴ According to the Quebec Task Force, “whiplash is an acceleration-deceleration mechanism of energy transfer to the neck. It may result from rear-end or side-impact motor vehicle collisions, but can also occur during diving or other mishaps. The impact may result in bony or soft tissue and neurologic injuries, which in turn may lead to a variety of clinical manifestations (whiplash associated disorders).”⁶⁵ Trigger points can contribute significantly to acute and/or chronic pain syndromes following vehicular impact which is a factor that is usually overlooked.⁶⁶ Cervical joint dysfunctions and TrPs are thought, by some authors, to be the most relevant sources of nociception in whiplash-related pain.⁶⁷

2.2. Initial Evaluation of Patients with Headache and/or Neck Pain

When a patient with head or neck pain seeks treatment, a thorough initial evaluation is needed to determine if this patient would be a candidate for TrP management. First, clinicians should record the pain history, pain features, and pain provoking or relieving maneuvers that increase or reduce head and/or neck symptoms. It is very important that clinicians pay close attention to reported symptom descriptors such as a pressing or a tightening quality which would indicate the presence and importance of referred pain from TrPs (see Box 17-1).

Postural assessment should include the position of the head on neck along with any other postural deviations that are relevant. This visual exploration is focused on postural abnormalities that can promote or perpetuate TrP activity of this musculature. Forward head posture⁶⁸ and anteriorly rounded shoulders are the two postural impairments most commonly observed in individuals with neck and/or head pain syndromes. These two postural abnormalities can promote a biomechanical disadvantage for the cervical

musculature that contributes to TrP activation.

Clinically, both TrPs and cervical joint hypomobility can contribute to head and neck pain syndromes. Clinicians should explore both inert and contractile structures in the initial evaluation. Muscles innervated by C1-C3 or the trigeminal nerve should be explored for the presence of TrPs. Specifically, the upper trapezius, sternocleidomastoid, masseter, splenius capitis and cervicis, semispinalis capitis, temporalis, levator scapulae, suboccipital, and superior oblique muscles should be examined for TrPs. Palpation of these muscles can be conducted by cross-fiber flat or cross-fiber pincer palpation (see specific muscle chapters for a description of these muscle examinations) with the aim of finding TrPs. Clinicians should focus their examination on reproduction of neck or head symptoms with palpation of TrPs. In some patients TrPs could also affect cervical ROM, but this impairment is not always present. Figure 18-1 shows the overlapping and composite referred pain patterns from TrPs in masticatory and cervical musculature.

Figure 18-1. Overlapping pain referral patterns (red) from TrPs in masticatory and cervical muscles producing typical unilateral or bilateral migraine or tension-type headache symptoms.

Examination of the upper cervical joints for ROM impairments and accessory joint motion is very important to identify as a possible source of symptoms or a contributing factor to the patient's head or neck pain. Many manual examination techniques are used for evaluating passive accessory joint motion of the cervical zygapophyseal joints. One of the most widely used methods is described by Maitland.⁶⁹ Jull et al⁷⁰ reported that assessment using intersegmental tests, as described by Maitland, could identify the presence and location of painful zygapophyseal joints with 100% sensitivity and specificity compared with the gold standard of diagnostic joint blocks. These authors included the following signs of a symptomatic cervical zygapophyseal joint: abnormal end feel, abnormal quality of resistance, and reproduction of the patients' symptoms. Because reproduction of the patient's complaint is considered one of the most reliable signs of symptomatic joint hypomobility,⁷¹ clinicians should focus the upper cervical joint examination on the reproduction of patient's symptoms. This is the same type of criterion used to clinically distinguish active from latent TrPs.

Based on the clinical signs found during the examination, management of a patient dealing with head or neck pain syndromes should focus on TrP management, cervical joint impairment, or both.

2.3. Trigger Points in Headache and Neck Pain

How Can Trigger Points Contribute to Headaches?

Several pain models explaining symptoms of headaches have been proposed. Olesen⁷² proposed that headaches might be due to an excess of nociceptive inputs from peripheral structures (eg, muscle, joints, or arteries). The trigeminocervical nucleus caudalis would play a central role in this model because perceived headache intensity would result from the sum of nociceptive inputs from cranial and extracranial tissues converging on the neurons of the nucleus caudalis. Figure 18-2 depicts the headache model proposed by Olesen⁷² where the roles of myofascial, supraspinal, and vascular inputs change depending on the headache.

Figure 18-2. Predicted importance of supraspinal, vascular, and myofascial inputs to brain-stem neurons in migraine and TTH. Some examples of the innumerable modulations of the vascular/supra-spinal/myogenic model of migraine and other headaches. S, supraspinal net effect (usually facilitation during headache); M, myofascial nociceptive input; V, vascular nociceptive input. Thickness of arrows represents the relative intensity of input. a, migraine aura without headache: despite strong vascular input there is no pain because of small S and M; b, migraine with aura: because of stronger supra-spinal or myofascial input the subject now suffers from headache; c, migraine without aura: the vascular input is not as strong as in migraine with aura, but the headache is no less intense because of a stronger supra-spinal facilitation or the combined effects of V and M. The latter case is likely to suffer alternating migrainous or TTH depending on small shifts in the relative magnitude of M and V; d, TTH: M is greater than V, and S is medium or large. Reprinted with permission from Olesen J. Clinical and patho-physiologic observations in migraine and tension-type headache explained by integration of vascular, supra-spinal and myofascial inputs. *Pain*. 1991;46:125–132.

In a posterior pain model, Bendtsen⁷³ suggested that the main problem in TTH is the sensitization of central pain pathways due to prolonged nociceptive inputs provoked by the liberation of algogenic substances and chemical mediator at the periphery from pericranial tender tissues. The presence of prolonged peripheral inputs can be of major importance for

the conversion of episodic into chronic TTH. This model explains the sensitization of central pathways, the increased supraspinal sensitivity, the increased muscle activity and hardness, the chronic pain, and the absence of objective signs of peripheral pathology in patients with chronic TTH. However, these models do not account for what initiates the central sensitization that is the source of the pain from the periphery.⁷⁴

Based on these pain models, the release of algogenic mediators in the peripheral tissues should be decisive for the sensitization mechanism. A recent study found no significant differences in change in interstitial concentrations of adenosine 5'-triphosphate (ATP), glutamate, bradykinin, prostaglandin E₂, glucose, pyruvate, and urea from baseline to exercise and postexercise periods between nonspecific tender spots of patients with chronic TTH and healthy patients. The study concludes that tender spots are not the peripheral structure responsible for the release of algogenic substances.⁷⁵ However, significantly higher levels of algogenic substances and lower pH levels have been recently found in active TrPs. Less significant levels have been found in latent TrPs or control spots (TrP-free muscle) demonstrating multiple reasons why active TrPs represent a peripheral sensitization focus.⁷⁶

Fernández de las Peñas et al⁷⁷ have suggested, in an updated pain model, that TTH can at least partly be explained by referred pain from active TrPs that is mediated through the spinal cord and the brainstem trigeminocervical nucleus caudalis.⁷⁷ Thus, active TrPs located in muscles innervated by C1-C3 or by the trigeminal nerve can be responsible for the peripheral nociceptive input and could produce a continuous afferent barrage into the trigeminal nerve nucleus caudalis. In fact, sensitization of nociceptive pain pathways in the central nervous system due to prolonged nociceptive stimuli from TrPs seems to be responsible for the conversion of episodic to chronic TTH.⁷⁸

Trigger Points and Migraine

Many patients are mistakenly diagnosed as having migraine when the problem is entirely TrPs. In others, TrPs are the triggers for initiating headaches that are assumed to be migraine in nature. Current theories, for true migraine, postulate that sensory pain features of migraine attacks may be attributed to the activation of the trigeminovascular system,^{50, 51} probably provoked by the peripheral liberation of algogenic substances.⁷⁹ The link between TrPs and migraine attacks could be the activation of the trigeminocervical nucleus caudalis or the trigeminovascular system provoked by the liberation of algogenic substances (ie, bradykinin, substance P, calcitonin gene-related peptide, tumor necrosis factor- α , serotonin, etc.) in the periphery caused by active TrPs.⁷⁶ Therefore, TrPs located in any muscle innervated by the trigeminal nerve (ie, extraocular or masticator muscles) or the upper cervical nerves (ie, upper trapezius, suboccipital, splenius capitis, sternocleidomastoid, etc.) may be viewed as “hidden irritative thorns” that precipitate, perpetuate, or aggravate migraine. Other triggers for migraine could also exist that are not yet identified.

Trigger points in several neck, shoulder, and head muscles have been found in patients with both unilateral⁸⁰ and bilateral⁸¹ migraine. In unilateral migraine, active TrPs were

located ipsilateral to migraine attacks as compared with the asymptomatic side⁸⁰; whereas in bilateral migraine without aura, active TrPs were located bilaterally.⁸¹ Furthermore, referred pain elicited by manual palpation of the superior oblique muscle (an extraocular muscle) has also been found on the symptomatic side in patients with unilateral migraine.⁸² These results have been confirmed in more recent studies where TrPs in neck muscles and hypomobility in the upper cervical facet joints were associated with migraine.⁸³ The referred pain elicited by active TrPs reproduced the pain features of migraine headache when patients were examined in a headache-free status. Table 18-1 details the muscles that had active TrPs in patients with migraine.

Table 18-1 Percentages of Active TrPs Found in Patients With Migraine	
Unilateral Migraine (Data Extracted From Fernández de las Peñas et al ^{80,82})	
Suboccipital muscles	25% active trigger points (TrPs)
Upper trapezius	30% active TrPs on the symptomatic side 5% active TrPs on the asymptomatic side
Sternocleidomastoid	45% active TrPs on the symptomatic side 5% active TrPs on the asymptomatic side
Temporalis muscle	40% active TrPs on the symptomatic side 0% active TrPs on the asymptomatic side
Superior oblique muscle	50% active TrPs on the symptomatic side 0% active TrPs on the asymptomatic side
Bilateral Migraine (Data Extracted From Calandre et al ⁸¹)	
Temporal area	42.6% active TrPs
Suboccipital muscles	33.4% active TrPs
Others (trapezius, masseter, etc)	24% active TrPs

Data for patients with unilateral migraine are based on a sample size of 20, and data for patients with bilateral migraine are based on a sample size of 98.

Another study demonstrated that patients with migraine who described having “imploding” (pain from inside to outside and pressing or tightening pain quality) or “ocular” (pain features in the ocular region) headache responded to injections of Botulinum Toxin A into several neck and head muscles (frontalis, upper trapezius, temporalis, semispinalis, and splenius capitis muscles).⁸⁴ The authors suggested that extracranial tissues may be involved in the pathogenesis of “imploding” or “ocular” migraine. Because pain features of patients with migraine are very similar to those characteristics of referred pain elicited by TrPs, others have suggested that TrPs are an etiologic factor for “imploding” or “ocular” migraine.⁸⁵

Based on the aforementioned studies, it appears that inactivation of TrPs in patients with migraine could offer additional pain relief. Furthermore, it has been demonstrated that inactivation of TrPs can relieve head pain in patients with migraine.^{86,87} These authors found that TrP inactivation was an effective palliative measure in the prophylactic management of severe refractory migraine and suggest that TrPs can be one of the hyperactive peripheral pain mechanisms linked to migraine predisposition. Therefore, TrP inactivation can reduce excitability of peripheral nociceptors and contribute to the amelioration of migraine attacks.⁸⁷

Trigger Points and Cervicogenic Headache

Headache originating in the cervical spine (cervicogenic headache) is a common clinical situation. It should be noted that controversy exists in the research and in the clinical community about a proper classification of this condition. It has been established that any structure (eg, muscle, joints, ligament, or tendon) innervated by the trigeminocervical nucleus caudalis can elicit referred pain to the head.⁸⁸ Some authors support the concept that cervicogenic headache is mainly provoked by referred pain from upper cervical joints^{89,90} rather than referred pain elicited by muscle tissues.⁹¹ Several studies have found that cervicogenic headache is caused by the presence of upper cervical spine dysfunctions.^{92,93} In these studies, head pain symptoms were reproduced by manual assessment of upper cervical joints (for clinical assessment of cervical joint dysfunctions see, Maitland⁶⁹). Furthermore, the effectiveness of spinal manipulation or mobilization procedures aimed at correcting upper cervical joint dysfunctions supports the concept that upper cervical joint dysfunctions can be more relevant for the pathogenesis of cervicogenic headache than for other headaches.^{67,94,95}

Features of this headache syndrome suggest that referred pain from TrPs can also contribute to the pain profile. Jaeger found, in a cohort of 11 cervicogenic headache sufferers, that all patients were found to have at least three TrPs on the symptomatic side.⁹⁶ The ipsilateral sternocleidomastoid and temporalis muscles were the muscles most affected by TrPs. Jaeger also found that those patients in whom TrPs were inactivated obtained a significant decrease in headache frequency and intensity, further supporting the role of TrPs in head pain perception in cervicogenic headache.⁹⁶ In addition, a case report found that referred pain from TrPs in the sternocleidomastoid muscle mimics the pain pattern of cervicogenic headache.⁹⁷ These authors demonstrated that the inactivation of TrPs in the sternocleidomastoid muscle was decisive for the relief of head symptoms in a patient in whom referred pain from other structures (eg, upper cervical joints) was not found. A pilot randomized controlled study found that manual therapy targeting sternocleidomastoid TrPs was effective in improving headache intensity, pressure sensitivity, cervical ROM, and motor performance of the deep cervical flexors in individuals with cervicogenic headache.⁹⁸

Several theories on muscle–joint interactions have been proposed. Perhaps the increased tension of the taut bands and facilitation of motor activity can produce sustained, increased and displacement stresses on the joint by TrPs to provoke and maintain joint

dysfunction.⁹⁹ The abnormal sensory input from the joint dysfunction may reflexively activate the TrP. Box 18-2 details some questions that may assist the clinician in determining whether head pain symptoms are related to upper cervical joint dysfunction or TrPs. Nevertheless, in some patients, pain from both joint dysfunctions and TrPs can occur simultaneously.

Box 18-2 Subjective questions to differentiate between neck pain arising from upper cervical joint dysfunction or trigger points (TrPs)

- Does your pain change with neck movement?
- Does your pain change with prolonged postures of the neck?
- Does your pain change with passive movement of the neck?
- Does the pain behind the eyes change with computer or TV use?
- Does the pain change following or during active movement?
- Does the pain change with muscle stretching?
- Was the onset of the pain gradual or acute?
- Does your pain feel superficial or deep?

Motor control impairment in the deep cervical flexor muscles has been reported in patients presenting with cervicogenic headache.¹⁰⁰ Deep cervical flexor impairment is usually associated with higher EMG amplitudes in the superficial neck flexors such as the anterior scalene or sternocleidomastoid muscles.¹⁰¹ An increase in EMG amplitude represents higher muscle activity during functional tasks of the cervical spine which would provoke muscle overload of these muscles. Therefore, motor control impairments of the deep cervical flexors may contribute to the development of TrPs in the superficial muscles from which referred pain can contribute to cervicogenic headache syndrome.

Trigger Points and Tension-Type Headache

Tension-type headache is the prototypical headache in which neck and/or shoulder muscles play an important role in the genesis of the pain.^{102–104} Individuals suffering from TTH described their head pain as pressing, tightening, dull, or as a generalized soreness^{105–107} which closely resembles the pain features of muscle referred pain elicited by TrPs.

Mercer et al found, in a non-controlled and nonblinded study, both active and latent TrPs in neck and shoulder muscles in individuals with TTH particularly in the splenius capitis or cervicis, semispinalis capitis or cervicis, levator scapulae, upper trapezius, and suboccipital muscles.¹⁰⁸ Marcus et al reported that individuals with TTH exhibit a greater number of either active or latent TrPs than healthy controls; these authors did not specify in which muscles TrPs were more frequently found.¹⁰⁹ Fernández de las Peñas et al found that either episodic or chronic TTH was associated with active TrPs in suboccipital,^{110,111} upper trapezius,¹¹² superior oblique,¹¹³ temporalis, and sternocleidomastoid

muscles.^{114,115} Table 18-2 summarizes which muscles were most commonly affected by TrPs in patients with TTH.

Table 18-2 Active TrPs Found in Patients With Both Chronic and Frequent Episodic Tension-Type Headache (TTH)	
Chronic TTH (Data Extracted From Fernández de las Peñas et al ^{110,114,129})	
Suboccipital muscles	65% active TrPs
Upper trapezius	24% active TrPs on the left side 36% active TrPs on the right side
Sternocleidomastoid	20% active TrPs on the left side 24% active TrPs on the right side
Temporalis muscle	32% active TrPs on the left side 36% active TrPs on the right side
Superior oblique muscle	86% active TrPs on both sides
Frequent Episodic TTH (Data Extracted From Fernández de las Peñas et al ^{111,115})	
Suboccipital muscles	60% active TrPs
Upper trapezius	33% active TrPs on the left side 14% active TrPs on the right side
Sternocleidomastoid	20% active TrPs on the left side 14% active TrPs on the right side
Temporalis muscle	40% active TrPs on the left side 46% active TrPs on the right side
Superior oblique muscle	15% active TrPs on both sides

It has also been found that TrP activity was related to headache pain perception in chronic but not episodic TTH. Patients with chronic TTH and active TrPs exhibit greater headache intensity and frequency than those with latent TrPs. However, headache pain parameters did not differ between episodic TTH with either active or latent TrPs. The fact that patients with chronic, but not episodic, TTH with pain-producing active TrPs had more severe headache pain characteristics than those patients with latent TrPs could be considered as result of temporal integration of signals from TrPs.¹¹⁶ Given that temporal summation of pain is centrally mediated,¹¹⁷ this would suggest a temporal integration of nociceptive signals from TrPs by central nociceptive neurons leading to sensitization of central pathways in chronic TTH.^{73,74} Finally, the fact that active TrPs are present in episodic TTH^{111,115} to a degree similar to chronic TTH^{110,112,114} does not support the

hypothesis that active TrPs are the consequence of central sensitization.¹¹⁸ Thus, it appears that, in addition to causing the well-known peripheral sensitization of nociceptive perception, TrPs can cause central sensitization, but central sensitization does not appear to cause TrPs. This is an important point because the two concepts are diametrically opposed and are central to two mutually exclusive ways of looking at the role of TrPs in TTH.¹¹⁹

Adoption of the term myogenic headache for headaches in which TrPs are etiologically important would underscore the importance of the concept of referred pain from active TrPs as a factor in headache development and emphasize the importance of treating these TrPs in the management of headache.

Mechanical Neck Pain

The presence of TrPs in patients with mechanical neck pain is often seen in clinical practice. Different studies have found that individuals with mechanical neck pain had active TrPs in neck–shoulder musculature, particularly the upper trapezius and levator scapulae muscles.^{120,121} The presence of TrPs in the upper trapezius muscle has been associated with cervical joint dysfunction at C3 and C4 levels.⁹⁹ Several theories on muscle–joint interrelationship have been proposed. Perhaps the increased tension of the taut bands and facilitation of motor activity can maintain displacement stress on the joint such that a TrP provokes and maintains joint dysfunction. However, an abnormal sensory input from joint dysfunction may reflexively activate the TrP. The mutual positive feedback between the presence of TrPs in the cervical musculature and the presence of cervical joint hypomobility support the importance of a thorough examination of both muscles and joints when assessing patients with mechanical or idiopathic neck pain. Well-designed studies investigating the therapeutic effect of treating TrP and joint disorders, either sequentially or in combination, are needed.

Whiplash

In a review of the whiplash literature, Fernández de las Peñas et al¹²² found that the most common muscles affected by TrPs were the scalene,¹²³ splenius capitis,¹²⁴ sternocleidomastoid,^{125,126} upper trapezius, posterior neck muscles,¹²⁷ and pectoralis minor muscles.¹²⁸ Treatment strategies including both TrPs and spinal joint interventions have been advocated for in the management of posttraumatic head and neck pain.¹²⁹ McMakin et al¹³⁰ demonstrated that treatment with frequency-specific micro-current can also be very helpful in reducing symptoms. The investigators first treated the neurologic dysfunction caused by the initial bruising of the brainstem and the spinal cord caused by the trauma and then treated the remaining active TrPs responsible for some of the pain complaints.

The biomechanical analysis of a rear-end impact shows mechanisms for activating TrPs. The S-shaped cervical curvature occurring during a rear-end impact may result in a lengthening position of the sternocleidomastoid muscle which produces a lengthening

contraction that overloads this muscle.¹³¹ A 6% lengthening¹³² or 179% of that produced by maximal voluntary contraction¹²⁴ of the sternocleidomastoid muscle has been described after rear-end impacts, a factor that readily explains TrPs in that muscle. Furthermore, deep cervical flexor impairment has also been found in patients with WAD.^{133–135} This motor control disorder is usually related to higher EMG amplitudes in the sternocleidomastoid and anterior scalene muscles which may also induce overload of the cervical spine musculature. A recent study observed that patients with whiplash exhibited a greater number of active TrPs than those with mechanical neck pain.¹³⁶ The number of active TrPs was significantly associated with the area and intensity of pain symptoms in patients with WAD.¹³⁶ Fernández Pérez et al¹³⁷ demonstrated that the number of active TrPs was associated with higher pain intensity and the number of days following the accident in patients with acute whiplash. This study also found that the number of active TrPs was associated with a higher localized pressure pain sensitivity at the cervical spine in this group of patients.¹³⁷

Several studies have demonstrated that patients with chronic whiplash pain develop more widespread hypersensitivity to mechanical pressure and thermal stimuli than those with chronic idiopathic neck pain¹³⁸ or healthy individuals.¹³⁹ These findings support the hypothesis that patients with WAD suffer from widespread hyperexcitability of the central nervous system.¹⁴⁰ Herren-Gerber et al found that central hypersensitivity was most likely dependent on local peripheral nociceptive input.¹⁴¹ Therefore, nociceptive sensitization by active TrPs could perpetuate sensitization of central pathways in patients with chronic whiplash pain.¹⁴² Nociceptive inputs from other structures (eg, zygapophyseal joint)¹⁴³ could also contribute to this central sensitization process. The results of the McMakin et al¹³⁰ study indicate that widespread pain hypersensitivity contributes to a central nervous system dysfunction initiated by the trauma. When these investigators normalized treatment of the central nervous system dysfunction, hypersensitivity disappeared. They also noted that inactivation of active TrPs is essential to reducing central hypersensitivity.¹³⁰

Based on the available data, it is postulated that the ongoing nociceptive input originated in active TrPs perpetuates or promotes sensitization of central pathways in head and neck syndromes. When this peripheral nociceptive input is identified and eliminated, the central sensitivity should be reduced. Because TrPs introduce ongoing peripheral nociceptive input,⁷⁶ inactivation of active TrPs should result in clinical improvement in patients with chronic TrPs¹²⁸ and in patients with acute, intractable TTH.

3. NEUROPATHIC PAIN SYNDROMES

From a clinical viewpoint, it is very important to distinguish between pain due to TrPs and that of neuropathic pain such as cranial or occipital neuralgias. Neuropathic pain is perceived as stabbing or shooting sensations occurring in paroxysms that follow the anatomic distribution of a nerve. In the head, the most common neuralgias are occipital and trigeminal neuralgia. Box 18-3 summarizes some common sources of head pain that are also common pain complaints from TrPs.

Box 18-3 Trigger points can contribute to the following neuropathic pain syndromes

Trigeminal neuralgia is a unilateral disorder characterized by brief electric shock-like pain, abrupt in onset and termination, limited to the distribution of one or more divisions of the trigeminal nerve.

Supraorbital neuralgia is a disorder characterized by paroxysmal or constant pain in the region of the supraorbital notch and medial aspect of the forehead in the area supplied by the supraorbital nerve.

Occipital neuralgia is a paroxysmal jabbing pain in the distribution of the greater or lesser occipital nerves or of the third occipital nerve, sometimes accompanied by diminished sensation or dysesthesia in the affected area.

Herpes zoster is a viral infection that can affect the trigeminal nerve manifesting itself as head or facial pain.

These definitions are based on the International Classification of Headache Disorders done by Headache classification Subcommittee of the International Headache Society.⁴⁷

Some patients presenting with occipital neuralgia described their pain pattern as burning or aching sensations, suggesting that referred pain from TrPs can mimic occipital neuralgia.¹⁴⁴ In some patients, pain in the occipital region may have an exclusive TrP origin. The occipital nerve can cross or penetrate the semispinalis capitis or upper trapezius muscles^{145, 146} and taut bands associated with TrPs in these muscles may entrap the greater occipital nerve which could account for some aching and referred frontal pain. Therefore, it is important that clinicians differentiate between symptoms resulting from occipital neuralgia, referred pain from TrPs, and upper cervical zygapophyseal joints.

Several authors have documented the relevance of TrPs in several neuralgias. Chen et al found the presence of TrPs in the intercostal muscles following an acute episode of herpes zoster in the intercostal nerve which responded well to TrP injection.¹⁴⁷ Ceneviz et al found, in a case report, that TrPs in the lateral pterygoid muscle can mimic pain features of trigeminal neuralgia.¹⁴⁸ Future studies are needed to determine the relevance of TrPs in these conditions and if their treatment is necessary or helpful for relief of cranial neuralgias.

Finally, chronic medication-overuse headaches can be caused by excessive use of analgesic medications such as aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs, or ergots. Clinical experience indicates that most patients with medication-overuse headache have active TrPs contributing to their head pain. Studies investigating TrP prevalence in this population are lacking and urgently needed.

Section 3

Upper Back, Shoulder, and Arm Pain

Levator Scapulae Muscle

“Crick in the Neck”

Derek L. Vraa, Michelle Finnegan, and Joseph M. Donnelly

1. INTRODUCTION

The levator scapulae muscle is unique in its anatomic structure and attachments to the cervical spine and the scapula. The proximal fibers originate from the posterior tubercles of C1-C4. It descends inferiorly and posterolaterally with the distal fibers attaching to the medial scapular border from the superior angle of the scapula to the scapular spine. This muscle has a unique posterior twist from its origin to its insertion such that the anteriorly facing fibers at the origin become the posterior facing fibers on insertion. The muscle is innervated by branches of the C3 and C4 spinal nerves and from C5 via the dorsal scapular nerve. The primary functions of the levator scapulae muscle are downward rotation and elevation of the scapula and ipsilateral cervical rotation. Bilaterally, it also plays a key role in stabilizing the cervical spine during neck flexion. The pain referral pattern of the levator scapulae muscle is to the angle of the neck and the interscapular and posterior shoulder regions. Activation and perpetuation of trigger points (TrPs) in the levator scapulae muscle are typically caused by holding the shoulders in an elevated and shortened position, especially when fatigued or from prolonged exposure to a cold draft. Because TrPs can present anywhere in the muscle, it is important to examine the entire muscle for the presence of TrPs. The levator scapulae muscle is frequently involved in headaches, mechanical neck pain, whiplash-associated disorders, scapular dysfunction, fibromyalgia, as well as shoulder pain and impingement. In addition, consideration should be given to this muscle when treating patients with jaw pain, cervical radicular symptoms, and upper extremity dysfunctions due to its actions and involvement in postural syndromes. Corrective actions including postural counseling at work and home (including sleeping postures) are paramount for successful treatment of TrPs in the levator scapulae muscle. Trigger point self-pressure release and gentle self-stretching exercises are part of a comprehensive treatment program.

2. ANATOMIC CONSIDERATIONS

The levator scapulae muscle is located at the floor of the posterior cervical triangle. The proximal fibers originate from the posterior tubercles of C1-C4. It descends inferiorly and posterolaterally, with the distal fibers attaching to the medial scapular border from the superior angle of the scapula to the scapular spine (Figure 19-1).¹ In a cadaveric study of 10 human specimens, the average length of the levator scapulae muscle was 15.1 cm with an average cross-sectional area of 2.18 sq cm.² The angulation of descent from the origin to the insertion varied from 30° to 45°. Muscle fiber composition of the levator scapulae muscle has not been studied.

Figure 19-1. Attachments of the levator scapulae muscle. Note how the upper and lower

digitations twist in their course from the superior attachment to the inferior attachment.

The views expressed herein are strictly those of the authors and do not represent the U.S. Air Force, the U.S. Department of Defense, or any other U.S. government entity.

One of the nuances rarely appreciated in the levator scapulae muscle is the subtle posterior twist of the fiber orientation as the muscle travels from its origin to insertion (Figure 19-1). MacBeth and Martin³ described the twist such that the superior fibers (C1) spiraled first laterally, then posteriorly, such that the anteriorly facing fibers at the origin become posteriorly facing on insertion. From C2 to C4, the fiber attachments originate posterior to the C1 fibers; however, as they spiral toward the insertion, the C2-C4 slips become deep to the C1 fibers. The biomechanical implications of this twist have not yet been fully studied.

Anatomic variations of the levator scapulae muscle are relatively uncommon, although some do exist. In a cadaveric study by Menachem et al,⁴ the muscle inserted in two layers enveloping the medial border attachment in 63% (19/30) of the shoulders of individuals examined. Of those, 14 presented with a bursa in the areolar tissue between the two layers. In addition, the authors found that in 43% (13/30) of the shoulders of individuals examined, there existed a narrow band of the serratus anterior muscle attached over the medial border of the scapula around its upper angle, close to the attachment of the levator scapulae muscle. Furthermore, in 38% (5/13) another bursa was located between the serratus anterior muscle, the angle of the scapula, and the levator scapulae muscle. It is important to recognize that these bursae are potential sources of pain and tenderness in this region. More recently, one cadaveric dissection reported a single case where the levator scapulae muscle had an accessory head that inserted into the ligamentum nuchae, tendon of the rhomboid major muscle, and the superior aspect of the serratus posterior superior muscle by way of a flat aponeurotic band.⁵

Other anatomic variances have been documented including variable attachments to the cervical spine. Chotai et al⁶ reported slips of the levator scapulae muscle attaching to the mastoid process. Bergman et al⁷ reported myofascial slips extending to the mastoid process of the temporal bones, the occipital bone, ligamentum nuchae, the clavicle, the first and the second ribs, and spinous processes of the thoracic vertebrae. In addition, slips have extended to the rhomboids, serratus anterior, serratus posterior superior, and trapezius muscles.⁷ MacBeth and Martin³ observed that the superior fibers of origin inserted on to the inferior one half of the supraspinous portion of the vertebral border of the scapula in 63% (54/80) of the cases with more- and less-extensive insertions on the remaining specimens.

2.1. Innervation and Vascularization

The levator scapulae muscle is innervated from two sources. The first is via branches from the C3 and C4 spinal nerves. The other innervation is from the brachial plexus (C5) via the dorsal scapular nerve.¹

Innervation of the levator scapulae muscle has consistent nerve pathways.⁸ From C3 to C4, an average of 1.92 branches from the cervical plexus remain deep to prevertebral fascia. These branches then emerge from under the posterior border of the sternocleidomastoid muscle, traveling in a cranial to caudal direction, to enter the posterior cervical triangle and innervate the levator scapulae muscle.

In the same cadaveric study, Frank et al⁸ also documented the innervation of the levator scapula muscle by the dorsal scapular nerve. Originating from the ventral rami of C5, the dorsal scapular nerve pierces the middle scalene muscle, entering the inferior portion of the posterior triangle of the neck. As the nerve enters the posterior triangle of the neck, it travels a variable distance in a posteroinferior direction. Interestingly, in 24 of the 35 cervical spines examined, on the path toward the rhomboid muscle, the dorsal scapular nerve drove deep to the anterior border of the levator scapulae muscle without any contributing branches to the muscle. In only nine of the cadavers did the dorsal scapular nerve directly enter the levator scapulae muscle, with two specimens receiving small branches. In a different study of 20 dorsal scapular nerves, however, all instances resulted in a direct innervation of the levator scapulae muscle.⁹ In a cadaveric study by Nguyen et al,¹⁰ differences in origination from the spinal root level, as well as what muscles it innervated, were demonstrated. They reported that 70% of the dorsal scapular nerves examined originated from the spinal root of C5, 22% arose from C4, and 8% from C6. The levator scapulae, rhomboid major, and rhomboid minor muscles were all innervated in 52% specimens. The dorsal scapular nerve innervated only the levator scapulae muscle in 48% of the specimens.

The levator scapulae muscle receives its primary vascular supply from the dorsal scapular artery. The dorsal scapular artery itself has been shown to arise from the second or third part of the subclavian artery in 70% of individuals,¹¹ whereas 30% arise from branches from the transverse cervical and ascending cervical arteries. Secondarily, the superior aspect of the muscle is supplied by branches from the vertebral artery.¹² Of note, the dorsal scapular nerve can be intertwined with the dorsal scapular artery.⁹

2.2. Function

The levator scapulae muscle elevates the scapula and assists with scapular downward rotation. It also has a role in scapular retraction, ipsilateral rotation and side-bending of the cervical spine, and postural positioning of the head. It almost always acts synergistically with other muscles to influence scapular mobility. These synergistic relationships are discussed below.

Electromyography (EMG) studies of the levator scapula muscle have demonstrated increased activity in scapular elevation, with moderate activity during scapular retraction.¹³ When moving the arm, the levator scapulae muscle assists scapular motion during shoulder elevation (abduction, flexion).¹⁴ In an EMG study by Behrsin and Maguire,¹⁵ the levator scapulae muscle was found to contract concentrically during the first 90° of shoulder abduction and eccentrically during the second 90°. Furthermore, it exerted more activity

during end ranges of flexion and abduction of the shoulder. This finding is consistent with that of Ludewig et al¹⁶ who demonstrated progressively increasing EMG activity of the levator scapulae muscle with increasing glenohumeral elevation as the scapula moves into upward rotation and posterior tilt. During sporting activities such as throwing or golf in which the shoulder is elevated, the levator scapulae muscle reaches a peak maximal voluntary isometric contraction (MVIC) of 33% to 72%.¹⁷

Magnusson¹⁸ demonstrated that the levator scapulae muscle plays a role in postural stability of the head and neck during low-speed, rear-end collisions. It was one of the first muscles to react when the impact came from the sagittal plane. A more recent study found that the levator scapulae muscle played a limited role in the stabilization of the head and neck during multidirectional perturbations.¹⁹

With the scapula stabilized, the levator scapulae muscle offers a minor contribution to ipsilateral side-bending and rotation of the cervical spine and a larger contribution in maintaining head position because it becomes active during resisted ipsilateral side-bending.²⁰ It has a reduced EMG activity when correcting for habitual postures such as forward head positioning and slouched positions.²¹

Dr Vladimir Janda²² described the Upper Crossed Syndrome (UCS) in which a patient presents with a classic forward head and rounded shoulder posture. In this syndrome, the levator scapulae muscle responds as tight and facilitated because it is a “postural muscle.” With the prolonged presence of the UCS, there is an increase in muscle tension that may then increase the probability of TrP development within the muscle and can potentially contribute to a number of dysfunctions in the upper quarter.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 19-1 grossly represents the functional unit of the levator scapulae muscle.²³

Box 19-1 Functional unit of the levator scapulae muscle

Action	Synergists	Antagonists
Scapular elevation	Upper trapezius Rhomboid minor Rhomboid major	Latissimus dorsi Lower trapezius Serratus anterior (lower fibers)

		Pectoralis minor
Scapular downward rotation	Latissimus dorsi Rhomboid major Rhomboid minor	Upper trapezius Lower trapezius Serratus anterior

Isometrically, the ipsilateral levator scapulae muscle becomes active with the ipsilateral upper trapezius and cervical spinal extensor muscles when resisting contralateral side-bending. The same muscles become active bilaterally, when acting isometrically, to retract and extend the head and neck.²⁴ With the scapulae stabilized, the muscle assists the sternocleidomastoid, splenius capitis and cervicis, scalenes, upper trapezius, and the erector spinae muscles with ipsilateral cervical side-bending.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points can be found in any portion of the muscle, although frequently they are found in the midportion of the muscle or close to the insertion at the scapula. Both areas refer pain at the angle of the neck^{25–27} with a spillover zone along the vertebral border of the scapula^{25, 27} and to the shoulder posteriorly^{25, 27–30} (Figure 19-2). If the TrPs are active, they can refer severe pain even at rest.

Figure 19-2. Consolidated referred pain pattern from TrPs in the right levator scapulae muscle. The essential pain pattern is solid red, and the spillover pattern is stippled red. The

entire muscle should be palpated for the presences of TrPs. Trigger points may be present very close to the attachment of the muscle at the superior angle of the scapula.

In clinical practice, the proximal half of the muscle often has TrPs relating to headaches and neck pain. In the distal half of the levator scapulae muscle, TrPs often produce pain in the posterior scapular region, often medial to the scapula but not crossing midline. In a study of 22 female patients with reports of shoulder pain over the superior medial angle of the scapula,⁴ 95% of the patients had maximum tenderness within 2 cm of the superior angle of the scapula. Pressing on the tender spot reproduced or increased their typical pain. In 73% patients, small nodules or crepitation was palpable at the tender spot, which the authors identified as TrPs. In the same study, pressing on the tender point produced neck pain in the cervical spine in 73% of the patients. Shoulder pain was elicited with TrP palpation in 50%, and upper limb pain was elicited in 23%. In addition to pain, when the levator scapulae muscle is involved, it consistently limits neck rotation due to pain with movement.

Trigger points can contribute to neck pain³¹ or shoulder pain³² with the levator scapulae muscle being one of the most commonly involved shoulder girdle muscles. In an older study of shoulder girdle muscles of 200 young adults, Sola³³ found the frequency of TrPs in levator scapulae muscles was second only to the upper trapezius muscle. In a separate clinical study of active TrPs in the upper quarter,³⁴ the levator scapulae muscle was the most commonly involved shoulder girdle muscle. More recently, Fernández de las Peñas et al³⁵ identified TrPs in the levator scapulae muscle of white- and blue-collar workers as the third most prevalent. Cerezo-Téllez et al³⁶ reported that TrPs in the levator scapulae muscles were the second most prevalent in those with nonspecific neck pain.

3.2. Symptoms

Patients with TrPs in the levator scapulae muscle may report symptoms in the cranial, cervical, and/or scapular regions depending on the location and severity of the TrPs. With severe involvement of the levator scapulae muscle alone, patients describe pain at the angle of the neck or as a stiff neck. The diagnosis of stiff neck syndrome or torticollis^{26,29} emphasizes the restriction of range of motion because tension in the levator scapulae muscle is a common cause of neck stiffness.^{26,29} Patients with TrPs in the levator scapulae muscle are unable to turn the head fully to the same side because of pain on contraction and not fully to the opposite side because of painful increase in muscle tension. They likely will turn their entire body to look behind (refer to clinical considerations in Chapter 33 for more on stiff neck).

Patients with mechanical neck pain and levator scapulae TrPs report cervical pain and a limited range of motion. They also describe a “deep” scapular pain with TrP palpation near the insertion of the muscle.^{37,38} Neoh³⁹ reported 75 patients describing a shortness of breath and nuchal soreness. Ninety percent of them were relieved of their symptoms after dry needling of levator scapulae TrPs.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Additionally, a complete medical screening should also be performed to rule out disease processes that can refer pain to the region of the levator scapulae muscle.⁴⁰

Postural examination from anterior, posterior, and lateral views may give cues to problems in the levator scapulae muscle. In particular, the clinician should assess for asymmetries of the head, neck, and scapular positions. Forward head posture with excessive upper cervical extension, or lateral flexion to one side, may indicate bilateral or unilateral muscle dysfunction, respectively. In forward head or flexed neck positions, tightness or TrPs in the levator scapulae muscle has the potential to interfere with upward rotation and posterior tipping of the scapula that is a requirement of normal scapular movement during shoulder elevation.⁴¹

Assessment of the range of motion in the cervical spine and shoulder in all planes is also recommended. Active neck rotation is most restricted as the face turns toward the side of the pain. The degree of restriction depends on the severity of involvement. When both sides are involved, as it commonly occurs, rotation can be markedly restricted in both directions. Neck flexion is blocked only at the end (extreme range) of the movement, whereas extension is relatively unaffected. If rotation of the neck is unrestricted, TrPs in the levator scapulae muscle are unlikely.

There is usually only a minimal limitation of shoulder motion. Full abduction requires full upward rotation of the scapula, which can be painfully restricted by TrPs in the levator scapulae muscle. The Apley's Scratch Test (flexion, lateral rotation, and abduction) is normal (see Figure 21-3).

Assessment of the cervical spine for accessory joint motion restrictions is essential because TrPs or muscle length deficits in the levator scapulae muscle can restrict movement of the cervical spine. Utilizing methods described by Cook⁴² have been shown to be valid and reliable.

It is also important to assess all joints of the shoulder complex. Because the muscle inserts onto the superior medial aspect of the scapula, it can directly affect scapulothoracic mobility, which can have an influence on the glenohumeral, acromioclavicular, and sternoclavicular joints. To accommodate for normal shoulder elevation and scapular motion, proper sternoclavicular and acromioclavicular coupling should occur.⁴³ Patients with shoulder pain demonstrate less sternoclavicular mobility.⁴³ Therefore, assessment of accessory joint mobility of the sternoclavicular and acromioclavicular joints should be incorporated into the examination process.

Loss of scapular upward rotation and anterior rotation has been noted as a potential contributor to shoulder impingement.^{16,41,44} Upward rotation and posterior tipping are necessary for normal shoulder elevation to prevent rotator cuff impingement on the lateral

aspects of the acromion.⁴⁵ Due to the line of action of the levator scapulae muscle, any TrPs, and even muscle tightening or muscle shortening, can have a potential effect on the scapular mobility. Increased tightening of the muscle pulls the scapula into a downward rotation and anteriorly tilted position. Therefore, shoulder pain could be a consequence of levator scapulae muscle dysfunction. Trigger points, as well as lowered pain pressure thresholds in the muscle, have been documented in patients with shoulder impingement syndrome.⁴⁶

Considering the coordinated activation of muscles involved in scapular motion, examination of the antagonistic and synergistic muscles should be performed. Trigger points are often associated with a reduced efficiency of reciprocal inhibition that may contribute to delayed and impaired muscle activation, thus contributing to faulty scapular mobility and potential levator scapulae TrPs.⁴⁷ Elimination of associated TrPs may then improve scapular motor control and reduce of pain in the levator scapulae muscle and its associated areas.

3.4. Trigger Point Examination

Examination of the levator scapulae muscle may be performed in side-lying with the symptomatic side upward, sitting, supine, or prone. However, side-lying or prone positioning is often more advantageous for the identification of TrPs as it allows for the relaxation of the head and neck, making identification easier.

The levator scapulae muscle commonly develops TrPs in two locations: a central area at the angle of the neck, where the muscle emerges from beneath the anterior border of the upper trapezius muscle,^{29, 48} and a much more readily identified secondary area close to where the muscle attaches to the superior angle of the scapula.^{48–50}

Trigger points in the levator scapulae muscle at the angle of the neck can be palpated with the patient comfortably seated in a chair, or preferably, with the patient lying on the uninvolved side. When the patient is sitting, both the levator scapulae and upper trapezius muscles are slackened slightly by supporting the elbows on armrests, using a folded towel if needed. Supporting the patient's arms allows for the clinician's fingers to push the upper trapezius muscle posteriorly far enough to uncover and straddle the levator scapulae muscle (Figure 19-3A, with the patient lying on the uninvolved side). Once identified, a cross-fiber flat palpation is utilized to identify TrPs in this portion of the muscle. Successful palpation depends on slackening the upper trapezius muscle sufficiently to reach the TrPs within the belly of the levator scapulae muscle without tensing that whole muscle so much that the difference between the taut band and the adjacent uninvolved muscle tissue is obscured.

Figure 19-3. A, Cross-fiber flat palpation of the levator scapulae at mid-muscle belly. B, Cross-fiber flat palpation of the levator scapulae at the superior angle of the scapula. C, Alternative technique with affected side down, utilizing cross-fiber pincer palpation.

To locate TrPs closer to its attachment at the scapula, the patient may be seated or preferably lying on the opposite side (Figure 19-3B). The muscle is palpated with a cross-fiber flat palpation above the superior angle of the scapula. Pincer palpation may also be used with the patient lying on the affected side (Figure 19-3C). The TrPs in this region are exquisitely tender to pressure; however, local twitch responses and referred pain are not readily elicited from this area which is covered by the trapezius muscle. The attachment region frequently feels indurated and tender and it can be rocked back and forth between the fingers when they straddle it. When the attachment has been stressed for a period of time, the area may feel gritty (like gravel) or like scar tissue.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the levator scapulae muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁵¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time, as in prolonged faulty postures or UCS (see Chapter 76). Patients who experience a whiplash injury are likely to

develop TrPs in the levator scapulae and other cervical muscles. In separate studies on whiplash injuries by Ettlin et al,⁵² Castaldo et al,⁵³ and Fernández-Pérez⁵⁴ researchers noted a high prevalence of TrPs in the levator scapulae muscle. Certain faulty ergonomic postures also contribute to the development of TrPs. Those who work at a desk⁴ and perform keyboarding with the head turned to one side, hold the phone between the ear and the shoulder, and/or speak at length with someone while the head is turned to the person at their side are likely to put stress on the levator scapulae muscle.⁵⁵ Those individuals who perform repetitive overhead activities such as throwers, swimmers, or volleyball players may have a tendency to develop more TrPs in the levator scapulae muscle; specific studies are needed to establish prevalence.

Another activating posture is sleeping with the neck in a tilted position that shortens the levator scapulae muscle, as in an uncomfortable seat, especially when the muscle is fatigued and exposed to a cold draft. Tilting the head while gazing fixedly at a stage, movie screen, or television can also precipitate the problem. Psychological stressors, which facilitate poor posture, may also be contributory.⁵⁵ Prolonged sitting in a chair with armrests that are too high elevates the scapulae and shortens the muscle bilaterally thus encouraging activation of TrPs. Walking with a cane that is too long, so that it forces unnatural elevation of one shoulder, tends to activate TrPs in the levator scapulae muscle on the same side.

The levator scapulae muscle can be overloaded and develop TrPs when the function of the serratus anterior muscle is inhibited by serratus anterior TrPs. Motor vehicle accidents and falls commonly activate levator scapulae TrPs due to acute overload stress.⁵⁶ Sometimes, TrPs in this muscle can arise secondarily from the activity of a primary TrP in the functionally related upper trapezius muscle.⁵⁷

4.2. Associated Trigger Points

In a study by Hsieh and colleagues,⁵⁸ associated TrPs may develop in the referred pain area from other TrPs. As a result, with TrPs in the levator scapulae muscle, muscles such as the upper and middle trapezius, rhomboids, serratus posterior superior, infraspinatus, supraspinatus, posterior deltoid, posterior cervical, semispinalis thoracis, and iliocostalis thoracis muscles can develop associated TrPs.

Associated TrPs in the levator scapulae muscle can be due to primary TrPs in the splenius cervicis, cervical multifidi, scalenes, middle trapezius, and the long head of the triceps muscles. Identifying which muscle is the source of symptoms is imperative, as deactivating these TrPs may also inactivate associated TrPs.⁵⁷ Trigger points within the midsection of the muscle are frequently found in conjunction with TrPs within the upper fibers of the trapezius muscle.

4.3. Associated Pathology

Trigger points in this muscle are associated with, or can mimic, many different conditions; therefore, a thorough medical screening and examination are essential. Trigger point

involvement of the levator scapulae, sternocleidomastoid, splenii capitis and cervicis, and upper trapezius muscles should be distinguished from spasmodic torticollis (cervical dystonia), which is a neurologic condition characterized by involuntary dystonic movements of the head^{59,60} that can be genetic, acquired, or idiopathic.⁶¹ Although the levator scapulae muscle is not as commonly involved as the sternocleidomastoid, trapezius, scalenes, and platysma muscles,⁶² making the differential diagnosis of this condition (against TrPs) is essential to ensure proper care. With spasmodic torticollis, hypertrophy of the muscles may develop.⁵⁹ In contrast, the apparent shortening of a muscle due to TrPs does not cause hypertrophy, nor does it cause involuntary movements of the head.

The levator scapulae muscle can contribute to headaches. Fernández de las Peñas⁶³ noted a high prevalence of TrPs in this muscle in patients who have tension-type headaches. Although the muscle typically does not refer pain to the craniofacial region, many patients with tension-type headaches present with neck pain and TrPs. Involvement of the levator scapulae muscle may also contribute to a shortening of the muscle as in UCS, which alters the craniovertebral angle and places individuals in a forward head posture. Patients with unilateral migraine often have forward head posture,⁶⁴ potentially contributing to migraine headaches. See clinical considerations in Chapter 33 for greater detail.

The levator scapulae muscle is involved in cervicogenic headache as well. Bogduk⁶⁵ discussed the involvement of the cervical spine and the trigeminocervical nucleus as a part of cervicogenic headaches. Because of the origins of the levator scapulae muscle, myofascial involvement within the muscle can restrict upper cervical spine mobility and thereby has the potential to contribute to the headaches. Moore⁶⁶ described a case in which UCS was noted with the patient who presented with cervicogenic headache. The presence of documented TrPs in the levator scapulae muscle was treated as part of a successful outcome. Furthermore, it is important to note that TrPs in the levator scapulae muscle may cause temporal and spatial summation of nociceptive input into the nervous system decreasing the pain threshold and increasing the probability for cervicogenic headache⁶⁴ (see clinical considerations in Chapter 33).

Facet/zygapophyseal joint dysfunction of the cervical spine can also cause pain in the same referral areas as the levator scapulae muscle,⁶⁷ specifically from C4 to C7. Clinically, it has been observed that hypomobility at C2-C3 can contribute to TrPs in the levator scapulae muscle. Assessment of articular causes of pain should be conducted by performing passive side-bending and rotation with the scapula elevated, which places the muscle on slack. Pain elicited during motion assessment while the muscle is in an antitension position is more likely to be of joint origin. Examination of accessory joint motion should also be utilized to assess for specific joint mobility loss and correlation of patient symptoms.

The levator scapulae muscle is frequently involved in those who have a “SICK scapula” or Scapular malposition, Inferior medial border prominence, Coracoid pain and malposition, and dysKinesis of scapular movement as described by Burkhart and colleagues.⁶⁸ This condition is most prevalent in overhead throwers. A key feature in the

SICK scapula is asymmetrical position and dyskinesia of the scapula, which in turn creates altered kinematics of the glenohumeral and acromioclavicular joints that affect the muscles that insert onto the scapula. As a result, the SICK scapula may play a role in a number of other diagnoses of the glenohumeral and acromioclavicular joints, including, but not limited to, subacromial impingement syndrome (SIS), superior labral anterior to posterior lesions, and instability. The levator scapulae muscle is frequently tender to palpation near its insertion. As a result, it is recommended to assess the scapula as described by Burkart and colleagues⁶⁸ and the levator scapulae muscle for TrP involvement in the SICK scapula. Furthermore, it is recommended that with this diagnosis all muscles attaching to the scapula be examined for TrPs as they will potentially affect scapular dyskinesia.⁴⁷

Studies have demonstrated that individuals with SIS have impaired scapular mechanics,⁶⁹ specifically a loss of upward rotation. The levator scapulae muscle perpetuates downward rotation of the scapula; therefore, shortening of this muscle or the presence of TrPs is likely to contribute to the loss of scapular mobility in SIS patients. It is currently unknown if the presence of SIS perpetuates the loss of scapular mobility or the loss of scapular mobility leads to SIS.

The levator scapulae muscle is innervated by C3-C4 spinal nerves and the dorsal scapular nerve (C5); therefore, it is important to identify these differences when performing a differential diagnosis for patients with upper quadrant pain and injury. Currently, no primary nerve or vascular entrapments due to TrPs in the levator scapulae muscle are reported.

5. CORRECTIVE ACTIONS

The consistent use of computers or tablets in bed or in a chair is likely to facilitate suboptimal posture and head and neck positioning. Correction of faulty posture can reduce reports of pain originating from the levator scapulae muscle. For example, reduction in excessive EMG activity in the upper trapezius muscle has been demonstrated through appropriate keyboard placement.⁷⁰ It is recommended that workstation ergonomic assessment and correction, use of proper seating, and use of assistive or supportive devices such as pillows or lumbar rolls be used in an attempt to reduce forward head posture.

Prolonged positioning contributes to the development of TrPs in as little as 1 hour of typing.⁷¹ Individuals who have an occupation that involves prolonged sitting and typing are recommended to relieve muscle tension 1 to 2 times per hour by simply standing and walking a short distance. Stretching the pectoralis major and minor muscles (refer to Chapters 42 and 43) can also assist in correcting posture and may improve scapular mobility.

Individuals who talk on a phone frequently during the day should avoid holding the phone to the ear with the hand or shoulder. The most effective solution is a headset with a microphone or other hands-free technology that removes the need for prolonged levator scapulae activation.

When turning over in bed, the patient should roll the head on the pillow instead of

lifting the head. When getting out of bed, the patient should roll onto one side and swing the legs off the bed to sit up, instead of pulling the trunk straight up because this action places additional strain on the levator scapulae muscles.

When using pillows at night to sleep, foam pillows tend to be more uncomfortable than softer pillows for patients with levator TrPs due to increased firmness and recoil. Pillows should not be placed under the shoulder but instead behind the neck to allow for proper support. Depending on the amount of kyphosis a patient has and the thickness of his or her pillows, 1 to 2 pillows should be appropriate. In a supine position, the proper thickness does not allow any extension of the head, but also does not place the head in excessive flexion, as this causes prolonged lengthening or shortening of the neck muscles during sleep. A small towel roll can be placed inside the pillowcase to support the neck in a neutral position, placing the face parallel to the ceiling. The patient can tuck the corner of the pillow between the shoulder and the chin (see Figure 7-5A) but not under the shoulder. For sleeping on the side, the pillow should be thick enough to keep the head and neck in a neutral position so that the head is not bent excessively to either side as this causes excessive lengthening of the muscle on the top side and excessive shortening of the muscle on the pillow side. The patient can tuck the corner of the pillow between the shoulder and the chin in the side-lying position as well (see Figure 7-5B) but not under the shoulder. Sleeping prone should be avoided due to the excessive shortening of the muscle on one side and excessive lengthening of the muscle on the other side. If one does sleep prone, a pillow placed under the shoulder and the chest on the same side to which the face is turned helps reduce rotation of the neck. A semiprone position, achieved by flexing the knee and the hip of the side toward which the face is turned, also helps by partially rotating the torso (see Figure 7-5C).

To deactivate TrPs in the levator scapulae muscle, a patient can perform self-pressure release of TrPs by using a TrP self-release tool (Figure 19-4A and B).

Figure 19-4. Trigger point self-pressure release. A, Attachment at scapula. B, Mid-muscle belly.

Stretching of the levator scapulae muscle can be performed with the patient in the seated or standing position. The arm is placed behind the back for the levator scapulae muscle that is involved. The head, is then rotated and side-bent to the opposite shoulder

while the hand on that side supports the weight of the head controlling head motion in a forward direction (Figure 19-5A). For a greater stretch, the hand supporting the weight of the head can be taken away and placed lightly on the top of the head to augment the stretch (Figure 19-5B).

Figure 19-5. Self-stretch. A, Supporting the weight of the head. B, Augmenting the stretch with a gentle overpressure.

Postisometric relaxation may also be utilized to augment the stretch. In the aforementioned position the patient takes a deep breath and with their eyes looks to the side being stretched holding for 6 seconds and slowly exhaling. Once the muscle relaxes, the supporting hand can slowly lower the head until increased tension is felt in the muscle. This technique can be repeated 3 to 6 times.

As mentioned previously, UCS results in facilitated or hypertonic levator scapulae muscles. This condition also results in weakened or inhibited lower trapezius and deep cervical flexor muscles. Strengthening or activation of these muscles in addition to stretching of the levator scapulae muscles is essential.

Scalene Muscles

“Pseudo-Radiculopathy”

Joseph M. Donnelly and Ingrid Allstrom Anderson

1. INTRODUCTION

The scalene muscles and the associated thoracic outlet entrapment syndrome (TOS) are often overlooked as a source of symptoms in patients with primary reports of pain, paresthesias, or dysesthesias in the upper extremity (UE). The scalene muscles have attachments throughout the cervical spine and to the first through the third ribs. All the scalene muscles are innervated by motor branches of the anterior primary divisions of spinal nerves C2 through C7 according to the segmental level of muscular attachment. Functionally, the scalene muscles stabilize the cervical spine against lateral movement and are well situated to elevate and stabilize the first and the second ribs during inhalation. The scalene muscles are one of 13 muscle groups that can refer pain to the medial border of the scapula. Referred pain from the scalene muscles can radiate anteriorly into the pectoral region; posteriorly to the medial border of the scapula; and laterally down the posterior arm, radial aspect of the forearm, and into the thumb and index finger. Patients may report pain as well as sensory and motor disturbances due to neurovascular entrapment. Distinctively, pain on the radial aspect of the hand is indicative of scalene involvement, whereas pain on the ulnar side of the hand with associated puffiness suggests brachial plexus and subclavian vein entrapment. Activation of scalene trigger points (TrPs) may result from excessive pulling and pushing, sporting activities, or chronic persistent coughing. Differential diagnosis includes C5-C6 radicular pain or radiculopathy, TOS, carpal tunnel syndrome, cervical spine dysfunction, and the first and/or second rib articular dysfunction. Entrapment of the lower trunk of the brachial plexus is a common result of TrPs in the scalenus anterior and medius muscles which can cause referred pain, paresthesia, and dysesthesia in an ulnar distribution in the UE and hand. Patients should be instructed on proper diaphragmatic breathing to decrease loading of the scalene muscles. Counsel regarding effective posture and positioning in sitting, standing, and lying positions is paramount to eliminate postural muscle strain. Ergonomic assessment of the work station is

essential along with proper neck-stretching exercises and maintenance of adequate body warmth.

2. ANATOMIC CONSIDERATIONS

The scalene muscles consist of three muscle pairs located on the lateral aspect of the neck, posteromedial, and deep to the sternocleidomastoid (SCM) muscles. These muscles have a considerable variety in their fiber direction and attachments, but they also have varying lengths and functions. Because of these anatomic differences, each of the scalene muscles are addressed individually in the following.

Scalenus Anterior

The scalenus anterior muscle originates from the anterior tubercles on the transverse processes of vertebrae C3 through C6. The fibers blend and travel inferolaterally to insert into the scalene tubercle on the inner border of the first rib and on the upper surface anterior to the groove for the subclavian artery (Figure 20-1).¹ The scalenus anterior muscle serves as an important landmark in the anterior neck as there are several important anatomic structures in this region. The phrenic nerve passes anterior to the scalenus anterior muscle. Posteriorly, the suprapleural membrane and pleura, the cervical roots of the brachial plexus, and the subclavian artery all separate the scalenus anterior muscle from the scalenus medius muscle. The vertebral artery and vein pass to and from the transverse foramen of the sixth cervical vertebrae just below the muscle's attachment to C6 medially between the longus colli muscle and scalenus anterior muscle.¹

Figure 20-1. Oblique view of the attachments of the three major scalene muscles to the cervical vertebrae and to the first and the second ribs. The clavicle has been cut and the section that overlies the scalene muscles removed.

Scalenus Medius

The scalenus medius muscle is the largest and the longest of the scalene muscles and originates from the posterior tubercles on the transverse processes of vertebrae C2 through C7 and occasionally to C1. The muscle slants diagonally and inserts onto the cranial

surface of the first rib, posteriorly to, and partly deep to, the groove for the subclavian artery (Figure 20-1). A slip of the muscle sometimes extends to the second rib. As noted above, in the scalenus anterior muscle these two muscles are separated by the subclavian artery and the ventral rami of the cervical nerve roots. Anteriorly, the clavicle and the omohyoid muscle cross over this muscle. The SCM muscle crosses posterolateral and the levator scapula and scalenus posterior muscles lie posterior to the scalenus medius muscle.¹ The anterior rami of C4, C5 C6, and C7 pierce the scalenus medius muscle in route to form the dorsal scapular nerve and thoracodorsal nerve, respectively.¹

Scalenus Posterior

The scalenus posterior muscle is the smallest and the deepest of the scalene muscles. This muscle originates from the posterior tubercles on the transverse processes of C4, C5, and C6, and inserts onto the lateral surface of the second rib just posterior to the attachment of the serratus anterior muscle and occasionally to the third rib. The scalenus posterior muscle crosses the first rib posterior to the scalenus medius muscle and deep to the anterior borders of the upper trapezius and levator scapulae muscles (Figure 20-1).

Scalenus Minimus

All the scalene muscles are variable in their attachments. The most variable is the scalenus minimus muscle that occurred on at least one side of the body in one third to three quarters of the individuals studied.²⁻⁴ This muscle usually originates from the anterior tubercle on the transverse process of vertebra C7, and sometimes also C6. It inserts onto the fascia supporting the pleural dome and beyond to the inner border of the first rib. The muscle lies deep to the scalenus anterior muscle and attaches posterior to the groove for the subclavian artery (Figure 20-2). The pleural dome, or cupola, is strengthened by the suprapleural membrane (Sibson's fascia) and anchored by this membrane to the anterior tubercle of C7 and the inner border of the first rib. The scalenus minimus muscle reinforces this fascia and can be up to 10 mm in diameter but is often much smaller.^{1, 2, 4}

Figure 20-2. Anterior view of the attachments of the scalenus minimus muscle (medium red), which lies behind the dark red subclavian artery (cut), whereas the scalenus anterior muscle lies in front of the artery. The artery passes over the first rib between these two muscles. Note how high into this region the dome of the pleura extends, where it is vulnerable to needle penetration.

The scalenus minimus passes beneath and behind the subclavian artery to attach to the first rib, whereas the anterior scalene muscle passes over and in front of the artery (Figure 20-2).⁴

2.1. Innervation and Vascularization

All the scalene muscles are innervated by motor branches of the anterior primary divisions of spinal nerves C2 through C7 according to the segmental level of muscular attachment. The scalenus anterior muscle is specifically innervated by the anterior primary rami of C4-C6 nerves. The scalenus medius muscle is innervated by the anterior primary rami of C3-C8 nerves. The scalenus posterior and scalenus minimus muscles are innervated by the anterior primary rami of C6-C8 nerves.¹

The vascular supply of all the scalene muscles comes from the ascending branch of the inferior thyroid artery. The scalenus posterior muscle also receives vascular supply from the superficial cervical artery.¹

2.2. Function

The scalene muscles function to stabilize the cervical spine against lateral movement, and they serve a primary role in respiration. Their specific actions are dependent on whether they are fixed from below or from above.

Fixed From Below

Acting unilaterally, the scalene muscles laterally flex the cervical spine,^{1,5} and when stimulated, they flex the head obliquely forward and sideways.⁶ All four scalene muscles are poorly placed to influence rotation of the neck significantly. Acting bilaterally, the anterior scalene muscles assist in neck flexion.¹ In a study by Olinger and Homier,⁷ seven cadaver specimens were examined using a mechanical approach to determine the function of the scalene muscles, specifically during cervical rotation. They concur with other authors that the primary function of the scalene muscles is to laterally flex the cervical spine ipsilaterally when contracting unilaterally and to assist with flexion of the cervical spine when acting bilaterally. Their model supports the notion that the anterior, middle, and posterior scalene muscles rotate the cervical spine ipsilaterally. Without stabilization of the cervical spine, the scalene muscles laterally flex the cervical spine ipsilaterally and elevate the first and the second ribs.⁷ The much flatter angle of the scalenus posterior muscle makes it especially suited to stabilizing the base of the neck by controlling transverse forces in a manner similar to the lowest diagonal fibers of the quadratus lumborum muscle at the base of the lumbar spine.

Fixed From Above

The scalene muscles have long been recognized as important auxiliary muscles of respiration and are more commonly used for respiration than are the SCM muscles.^{8,9}

Electromyographic and muscle stimulation evidence supports elevation of the first and the second ribs during inspiration as a primary function, not just an accessory inspiratory function, especially the scalenus medius muscle.^{1,6,10} The scalene muscles are active in normal quiet inhalation, though activation may be higher in those with a costal breathing pattern versus diaphragmatic breathing.^{11,12} Scalenotomy causes an immediate decrease in the vital capacity, but considerable recovery occurs later.⁸ When present, the scalenus minimus should also be effective for inhalation which may explain its hypertrophy in some persons. The scalene muscles often contract to stabilize the cervical spine when people carry, lift, or pull heavy objects.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 20-1 grossly represents the functional unit of the scalene muscles.¹³

Box 20-1 Functional unit of the scalene muscle		
Action	Synergists	Antagonist
Cervical lateral flexion	Sternocleidomastoid Longissimus capitis Cervical multifidi	Scalenes (contralateral) Sternocleidomastoid (contralateral)
Inspiration	Diaphragm External intercostal Sternocleidomastoid	Rectus abdominis External abdominal oblique Internal abdominal oblique Internal intercostal

During labored breathing, the upper trapezius,⁸ levator scapulae, and omohyoid muscles can assist inhalation by elevation of the shoulder that helps lift the weight of the shoulder girdle off the chest wall. The pectoralis minor muscle has a synergistic function with the scalene muscles for the elevation of the ribs when the scapula is stabilized.⁸

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the anterior, medial, or posterior scalene muscles may refer pain anteriorly

to the chest, laterally to the upper limb, and posteriorly to the medial scapular border and adjacent interscapular region (Figure 20-3A).^{9,14,15} It is important to remember that any one of the scalene muscles can produce any part of the referred pain pattern.

Figure 20-3. Composite pain patterns (solid red areas are the essential pain reference zones, and stippled red areas are the spillover reference zones) in the right scalene muscles (medium red). A, Scalenus anterior, medius, and posterior. Some TrPs may have only one essential reference zone. B, Scalenus minimus.

Posteriorly, pain is commonly referred from TrPs in the scalenus anterior muscle to the back, over the upper half of the vertebral border of the scapula, and to the adjacent interscapular region.¹⁶ When the patient presents with posterior shoulder pain, particularly

along the border of the scapula, one should be sure to check for scalene TrPs as they are one of the most common sources of this type of pain reported by patients.

Anteriorly, persistent aching pain is referred in two finger-like projections over the pectoral region down to about the nipple level.¹⁷ This pattern commonly originates in the lower part of the scalenus medius or scalenus posterior muscle. Scalene pain referred to the anterior shoulder region is not characteristically described as deep in the joint, as is the pain referred from the infraspinatus muscle. It is often described as a tightness or a grabbing sensation, and on the left side of the thorax, this TrP referred pain may be mistaken for angina pectoris because it is likely to be associated with muscular activity.

Referred pain from the scalene muscles may extend down the front and back of the arm (over the biceps and triceps brachii muscles).¹⁶ The referred pain often skips the elbow and reappears in the radial side of the forearm, the thumb, and the index finger. This upper limb pattern arises from TrPs in the scalenus anterior and scalenus medius muscles.

The less frequently seen pain referred from TrPs in the variable scalenus minimus muscle projects strongly to the thumb (Figure 20-3B). This pain covers the lateral aspect of the arm from the deltoid insertion to the elbow but skips the elbow to cover the dorsum of the forearm, wrist, hand, and all the five digits, accenting the thumb. Trigger points may refer a sensation that the patient describes as “numbness” of the thumb with or without demonstrable hypoesthesia to cold or touch.

Experimental injection of 0.2 to 0.5 mL of a 6% solution of sodium chloride into the scalenus anterior in seven subjects evoked referred pain primarily in the shoulder region in all subjects, pain down the arm in one subject, and a superficial hyperesthesia radiating upward over the neck in two subjects.¹⁸

3.2. Symptoms

Scalene TrPs should be considered as a source of symptoms in patients presenting with UE pain, paresthesias, or dysesthesias because TrPs in these muscles are a common source of neck, shoulder, and arm pain. Pain arising from TrPs in the scalene muscles is often underdiagnosed or misdiagnosed.^{19,20} The most common diagnoses for symptoms associated with scalene myofascial pain is cervical disc pathology, cervical spondylosis, and TOS. Symptoms related to TOS are thoroughly addressed in Chapter 33. All these aforementioned conditions can cause neck and UE pain, paresthesias, and/or dysesthesias. Although scalene TrPs only occasionally refer pain to the head, they are commonly associated with TrPs in other muscles that do and therefore should be considered when a patient reports neck and head pain. In patients who report shoulder, medial border of scapula, and UE symptoms, TrPs in the scalene muscles should be considered. Patients may report pain and paresthesias that radiate into the lateral aspect of the hand. When the primary patient report is of UE pain that mimics C4-C7 radicular symptoms, the scalene muscles (especially the scalenus anterior and medius muscles) should be considered for specific examination.²⁰

In a study by Jaeger et al, more than half of 11 patients with cervicogenic headache also

had associated active scalene TrPs that contributed to their pain.²¹ In another recent study, increased mechanical sensitivity in the scalene muscles was noted in women with migraine headaches.²² Of 72 patients with nontraumatic shoulder pain, active and latent TrPs were found in 12 and 17 individuals, respectively.²³ In a patient with a UE amputation, this referred pattern of the upper limb pain produced severe phantom limb pain that was relieved by one author²⁴ by the inactivation of scalene TrPs. Sherman²⁵ lists the elimination of TrPs as one treatment for relief of phantom limb pain.

When the patient reports pain in the upper back just medial to the superior angle of the scapula, the most likely myofascial source of these symptoms is a scalene TrP. Patients with TrPs in the scalene muscles sometimes speak of their “shoulder” pain while indicating the upper half of the arm. Sleep is often disturbed by pain. When the night pain is severe, the patient is likely to sleep sitting up on a sofa or propped up on pillows for relief. This position helps prevent the sustained shortening of the scalene muscles that tends to occur when the patient lies flat and the chest and the shoulders are elevated during sleep, particularly with an inappropriate pillow.

Neurologic symptoms of numbness and tingling in the hand (chiefly in the ulnar distribution) and the unexpected dropping of objects from the hand can result from the entrapment of the lower trunk of the brachial plexus. It exits the thorax by hooking over the first rib, indicating possible compression of the neurovascular bundle by the pectoralis minor muscle (refer to Chapter 33 for more clinical considerations).

Patients may also report swelling in the hand that, when present, appears diffusely distal to the wrist, particularly over the bases of the four fingers and the dorsum of the hand. Patients are likely to experience puffiness of the dorsum of the hand, stiffness of the fingers, and tightness of rings on fingers especially in the morning on waking. These symptoms are likely to be caused by entrapment of the subclavian vein and/or lymph duct as they pass across the first rib in front of the attachment of the scalenus anterior muscle. Scalene TrPs should be considered as a contributing factor to this entrapment. The swelling or reported puffiness may dissipate later in the day. The associated stiffness of the fingers is not solely due to the edema but also to myofascial tautness of the finger extensors that may have an autonomic reflex component.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. In patients who report a history of falling or a motor vehicle accident, examination of the scalene and SCM muscles is a high priority. For proper examination of the scalene muscles, the clinician should observe head and neck postures, shoulder girdle posture, active and passive range of motion of the cervical spine, and the position and mobility of the first and the second ribs. It is extremely important to examine postures during functional activities because habitual postures or activities that

require positioning the head off the center may overload the scalene muscles.

Cervical range of motion should be assessed using appropriate caution to avoid vertebral artery compromise. Neck rotation is painful only at the extreme range of motion to the same side, although it may not be painful because motion may be slightly restricted before the painful end range is reached. While the subject's neck is side-bent, the clinician should slowly and gently move the patient's head and neck into varying degrees of rotation. This maneuver often elicits increased pain or the report of a "tight feeling." If the patient is then instructed to point to the troublesome area, the clinician can use that as a starting point to palpate for TrPs. Side-bending of the neck to the opposite side is usually restricted if scalene TrPs are present. Scalene muscle involvement itself causes no restriction of motion at the glenohumeral joint, and pain is not significantly increased by tests of shoulder motion. However, the resultant first rib mobility deficits may cause a feeling of restricted shoulder elevation.

Scalene TrP activity alone causes a minimum restriction of neck rotation, whereas TrPs in the levator scapulae and splenius cervicis muscles markedly limit cervical rotation. Scalene TrPs are more closely associated with limited cervical side-bending and when moving the head in a combined cervical flexion, side-bending, and rotation pattern. Patients with a scalene myofascial pain syndrome tend to move the arm and neck restlessly, as if trying to relieve a "sore" muscle.

Diaphragmatic breathing should also be assessed because the scalene muscles function to elevate the first and the second ribs during inhalation. Inefficient respiration (chest breathing) is a contributing factor to scalene TrPs because this muscle activation pattern overly stresses the scalene muscles. In patients with chronic obstructive pulmonary disease, post bronchitis, or pneumonia, scalene TrPs are very common because the scalene muscles are overworked during inspiration.

Accessory joint motion should be tested in the cervical spine, the first and second ribs, acromioclavicular joint, sternoclavicular joint, and scapulothoracic joints. Seen clinically, joint hypomobility in the first and the second ribs can cause impairment in shoulder elevation contributing to alterations in normal muscle activation patterns. Articular dysfunctions in the cervical facet joints (C2-T1) and uncovertebral joints may also impair muscle activation patterns contributing to overload of the scalene muscles.

Travell and Simons described three tests they commonly utilized to identify scalene TrPs.¹³ These tests include the scalene cramp test, scalene relief test, and the finger flexion test. The clinical utility of these tests have not been investigated; anecdotally, they appear to assist the clinician in the differential diagnosis of myofascial pain caused by scalene TrPs.

Scalene Cramp Test

To perform this test, the patient rotates the head fully to the side of the pain and actively pulls the chin down into the hollow above the clavicle by flexing the head and the neck (Figure 20-4), holding this position up to 60 seconds. During the last part of this movement, the anterior and the middle scalene muscles strongly contract while in the

shortened position. This evokes a local cramp-like pain in the region of the TrP and may further activate the TrP causing continuing moderate or severe pain referred from it. If the patient was already in severe pain before attempting the test movement, the test result may not appear clearly positive because the patient does not perceive the additional pain caused by the test. In this situation of an existing severe pain, the Scalene Relief Test (Figure 20-5) should be tried first.

Figure 20-4. The Scalene Cramp Test elicits or increases pain from TrPs in the scalene muscles. A, The head rotates fully to the left side to test left scalene muscles. B, The chin dips down into the hollow behind the clavicle. This hard contraction in the shortened position of scalene muscles (with TrPs) causes a local ache at the TrP and pain that may be referred to a distance, as illustrated in Figure 20-3.

Figure 20-5. The scalene relief position helps identify the scalene TrPs source of referred pain that is caused or aggravated by clavicular pressure on the nerves passing over the elevated first rib or on an involved muscle. Clearance beneath the clavicle is maximized by swinging the shoulder forward, which protracts the scapula and pivots the clavicle forward and

upward to fully relieve the clavicular pressure on neurovascular structures. Pain relief by this test should occur immediately or within a few minutes.

Scalene Relief Position

Referred pain from scalene TrPs may be relieved by the elevation of the arm and the clavicle²⁶ because this maneuver may remove pressure from structures traversing or attaching to the first rib (which can be elevated by TrP-shortened scalene muscles). The scalene relief position makes use of this principle. The patient places the painful forearm across the forehead while raising and pulling the shoulder *forward* to lift the clavicle off the underlying scalene muscles and brachial plexus (Figure 20-5). Pain relief, when it occurs, ensues immediately or within a few minutes. This position should not be confused with the shoulder abduction test as described by Wainner et al,²⁷ which is part of a test item cluster to rule in cervical radicular symptoms.

Finger Flexion Test

This test of finger flexion should be performed with the metacarpophalangeal (MCP) joints actively held straight in full extension. This position requires forceful contraction of the extensor digitorum muscle, but the tightly closed fist does not. The test is normal when the fingertips can firmly touch the volar pads of the MCP joints (Figure 20-6A). If one or more compartments of the extensor digitorum muscle have TrPs, each corresponding finger fails to flex completely. Figure 20-6B shows a positive test for TrPs in the extensor of the index finger. Voluntary hyperextension of the MCP joints strongly loads the finger extensors, increasing the activity of these TrPs. This TrP activity apparently reflexively limits simultaneous distal interphalangeal flexion by inhibiting the corresponding finger flexor.

Figure 20-6. Finger flexion test. A, Normal finger closure with all fingers flexed tightly. B, Positive test for finger extensor muscle dysfunction. C, Positive scalene test, incomplete flexion of all fingers.

The test is also positive when TrPs are present in the scalene muscles. In this case, all four fingertips may fail to touch the MCP volar pads (Figure 20-6C). However, there is no difficulty in making a tight fist when the MCP joints are allowed to flex. Apparently, TrPs

in the scalene muscles similarly inhibit finger flexors when the MCP joints are extended. Scalene TrPs are frequently the key to forearm extensor digitorum TrPs. The referred motor effects of TrPs are frequently independent of, and can affect different locations than, referred sensory effects.

A positive test is not simply due to edema, because this test of distal interphalangeal flexion is frequently restored to normal immediately after the treatment of the involved scalene muscles. Furthermore, edema is more likely to occur only with the involvement of the scalenus anterior, whereas active TrPs in any of the scalene muscles may be responsible for an abnormal finger flexion test.

3.4. Trigger Point Examination

The localized twitch response is difficult to elicit manually in the anterior and middle scalene muscles and very difficult in the posterior scalene muscle. Based on the location and the data on the interrater reliability of TrP palpation, as well as the anatomic location of the scalene muscles, the detection of a taut band, a hyperirritable spot, and referred pain are the most reliable diagnostic criteria. Local twitch responses are characteristically elicited when a needle encounters the TrP. It can be depended on only as a diagnostically confirmatory finding.

When trying to locate the anterior and middle scalene muscles, it is helpful to remember that the digitations of the anterior scalene muscle attach to the anterior tubercles of the cervical vertebrae, the brachial plexus emerges between the anterior and posterior tubercles, and the fibers of the middle scalene muscle attach to the posterior tubercles. The brachial plexus descends in a palpable groove between the two muscles and becomes progressively more superficial to emerge from between the two muscles to exit the neck and thorax by crossing over the first rib. First, palpating the SCM muscle and finding the subclavian artery are the most reliable methods of locating the scalene muscles.

The TrPs in the scalenus anterior muscle are found by palpating the muscle behind the posterior border of the clavicular division of the SCM muscle. The posterior SCM border can be approximated by locating the external jugular vein with finger pressure just above the clavicle (Figure 20-8A). The omohyoid muscle is more superficial than the scalene muscles, emerges from behind the SCM muscle, and crosses diagonally over the anterior scalene. It can cross at about the same level as the scalene TrPs depending on which scalene digitation is involved and depending on the head and UE position. The omohyoid muscle tends to be thinner than the scalene muscles. To differentiate the scalene muscles from other structures, the patient should be asked to take a deep sniff through their nose. This action causes a significant contraction of the scalene muscles. If the inferior belly of the omohyoid muscle has a tender TrP and taut bands, it can easily be mistaken for the scalenus anterior muscle despite these muscles having different fiber directions (Figure 20-7). These TrPs frequently exist together as discussed earlier, and differentiation can be important in the treatment of whiplash-associated disorder (WAD) and TOS.

Figure 20-7. Neighboring muscles (medium red) that are useful landmarks in locating the scalene muscles (dark red). The inferior belly of the omohyoid muscle is easily mistaken for the anterior scalene muscle although they do not have the same fiber direction. It is superficial and is located where one could expect to find the scalene muscle.

The patient should be positioned supine with the head slightly rotated in the contralateral direction with the cervical lordosis supported (Figure 20-8). The scalenus anterior muscle can be identified by positioning the patient's head to take up any slack in the muscle and then palpating its anterior and posterior borders. Its posterior border is confirmed by locating the groove between the anterior and middle scalene muscles that cradles the brachial plexus bundle of nerve fibers. In this groove, behind the clavicle, the subclavian artery is nearly always palpable where it passes between these two muscles to cross over the first rib (Figure 20-9). The fingers of one hand straddle the scalenus anterior muscle to establish its location, while the other hand utilizes cross-fiber flat palpation to precisely localize taut bands and TrPs (Figure 20-8).

Figure 20-8. Palpation of anterior and middle scalene muscles between the sternocleidomastoid muscle anteriorly and the levator scapulae and upper trapezius muscles posteriorly.

Figure 20-9. Thoracic outlet entrapment by the scalene muscles (medium red). The neurovascular bundle is spread out to show the relations of its component parts. A portion of the clavicle has been removed. The brachial plexus and subclavian artery (dark red) emerge above the first rib and behind the clavicle between the scalenus anterior and scalenus medius muscles. The spinal nerves are numbered on the left, the vertebrae on the right. The T1 nerve lies dorsal to and beneath the subclavian artery. These structures crossing over the first rib can be compressed when the rib becomes elevated. Trigger points in the scalenus anterior and/or the scalenus medius muscles are associated with taut bands

that increase muscle tension and elevate the first rib, compressing the neurovascular structures.

The scalenus medius muscle is parallel to, and on the posterior side of, the groove described above that contains the bundle of brachial plexus nerve fibers. It is wider than the scalenus anterior muscle and lies anterior to the free border of the upper trapezius muscle (Figure 20-7). It can be palpated against the posterior tubercles of the transverse processes of the vertebrae utilizing cross-fiber flat palpation. Palpation should be carried out very carefully due to the neurovascular structures in the region. The sniff test can be utilized to identify the scalenus medius muscle.

The scalenus posterior muscle lies more horizontal than, and dorsal to, the scalenus medius muscle. It passes anterior to the levator scapula muscle, which should be pushed aside at the point where the levator scapula muscle emerges near the free anterior border of the upper trapezius muscle (Figure 20-7). Finding TrP tenderness requires cross-fiber flat palpation posterior to the scalenus medius muscle and to the depth of the first rib. This attachment is often tender in the absence of TrPs in the muscle belly.

Because of the location and variance of the scalenus minimus muscle in terms of existence, composition, and size, reliable TrP palpation is difficult. It may manifest into residual tenderness in the scalenus anterior muscle following treatment.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the scalene muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁸ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. Side-sleeping without proper pillow support or sleeping supine with too many pillows may place the scalene muscles in a shortened or lengthened position.

Scalene TrPs are common following a cold with a bad cough, pneumonia, bronchitis, or allergies as all these conditions require the scalene muscles to be overloaded due to their respiratory functions. Scalene TrPs may also be activated by a fall or motor vehicle accident, prolonged pushing or pulling, or lifting and carrying awkwardly large objects with the UEs. Hiking with a heavy backpack for long hours is particularly demanding on the scalene muscles in addition to the upper trapezius, SCM, and pectoralis minor muscles. Playing handheld string instruments such as the violin or wind instruments such as the flute, which require a tilted head and neck position for proper use, may activate scalene TrPs. Swimming may also place the scalene muscles at risk for developing TrPs due to the cardiorespiratory demands, repetitive cervical spine rotation, and UE use.²⁹

Biomechanical malalignment such as a tilted shoulder girdle axis due to a leg length discrepancy when standing, a small hemi-pelvis when seated, and a structural or functional

scoliosis may also place the scalene muscles at a mechanical disadvantage and overload them. Changes in the rib cage that are common with a structural scoliosis may place increased demands on the scalene muscles during inspiration. Habitual chest breathing and poor diaphragmatic breathing patterns cause repetitive overload in the scalene muscles leading to TrP formation.

Prolonged computer work with improper or awkward workstation setup where an individual spends hours each day with the dominant arm in an elevated, abducted, and slightly internally rotated position while using a mouse can shorten and activate TrPs in all three or four scalene muscles. Visual stressors during computer work may also contribute to TrP formation as this causes an alteration in the head position from a centered neutral posture.³⁰ In addition, prolonged flexion and side-bending of the neck to hold a phone between the head and a slightly elevated shoulder contributes to the formation of scalene TrPs.

A whiplash-type injury from a motor vehicle accident is likely to activate TrPs in the scalene muscles in addition to several other muscles in the cervical spine and shoulder girdle. In a study by Hong et al, 81% of patients with WAD with a report of pain had at least one active scalene TrP.³¹ In a more recent study, Fernandez-Perez et al investigated the prevalence of TrPs in patients with WAD and healthy controls. In individuals with acute WAD they found a high prevalence of active and latent TrPs compared with those in a healthy control group. They also found that subjects with acute WAD and higher levels of disability had more active TrPs resulting in higher reports of pain and widespread pressure hypersensitivity.³²

The scalene muscles can be affected by movement impairments that produce a severe deviation from the normal pattern of gait. An antalgic gait pattern or limping on a weight-bearing lower extremity (with resultant torso and head adjustments) and lack of normal push-off at the end of the stance phase can activate TrPs in the scalene (and levator scapulae and SCM) muscles, because those muscles contract excessively in their reflexive attempt to compensate for, and/or maintain, equilibrium and efficiency of movement.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.³³ Therefore, muscles in the referred pain areas of the scalene muscles should also be considered. The scalenus anterior and medius muscles are often involved together. When the scalenus minimus is involved or has TrPs, all the scalene muscles are usually affected. Scalene TrPs are often activated by TrPs in the SCM muscle, which form a functional unit with the scalene muscles. The SCM muscle is also an important part of the functional unit for vigorous or labored inhalation and is therefore likely to become involved if scalene TrPs have been active or present for a considerable period of time. Trigger points in the scalenus medius muscle are likely to be found in association with TrPs in the upper trapezius, SCM, and splenius capitis muscles.³⁴

Associated TrPs may develop in several of the areas to which the scalene muscles refer

pain. Both the pectoralis major and minor muscles commonly develop TrPs in regions that correspond to the scalene-referred pattern of anterior chest pain. Associated TrPs may also be found in the rhomboids, middle trapezius, and infraspinatus muscles due to the referral of pain from scalene muscles to the medial border of the scapula. Associated TrPs in the long head of the triceps brachii correspond to the scalene pattern of the posterior arm pain, and those in the deltoid muscle correspond to the anterior pattern.^{23,31} Although the dorsal forearm is a less common site of scalene-referred pain, associated TrPs tend to develop in the extensor carpi radialis, extensor digitorum, extensor carpi ulnaris,³⁵ and brachioradialis muscles. When TrPs in the lateral part of the brachialis muscle are induced from scalene TrPs, both the brachialis and scalene muscles refer pain to the thumb, making this digit especially painful.

When the omohyoid muscle (see Chapter 12) develops TrPs and becomes tense, it can act as a constricting band across the brachial plexus.³⁶ Because the tense muscle stands out prominently when the head is side-bent to the contralateral side, it can be mistaken for the upper trapezius or a scalene muscle. When the omohyoid has TrPs, it can prevent full stretch of the trapezius and/or scalene muscles and therefore should also be released.

In individuals with a primary report of shoulder pain, scalene TrPs are likely to coexist with those in the rotator cuff, deltoid, biceps brachii, and triceps brachii muscles.³⁷ The pain from these muscles may correspond to the referred pain pattern of the scalene muscles.

4.3. Associated Pathology

Trigger points in the scalene muscles are associated with and can mimic a variety of different conditions that cause UE symptoms including TOS, scalenus anticus syndrome, C5 and C6 radicular pain and/or radiculopathy, poor posture, and carpal tunnel syndrome. It is essential to perform a thorough medical screening and examination to determine if referral to another healthcare practitioner is necessary. Appropriate medical management should be utilized to reduce the excessive demand on auxiliary muscles of respiration that is caused by coughing and sneezing (eg, in patients with allergic rhinitis, bronchitis, pneumonia, emphysema, asthma, and sinusitis).

The scalenus anticus (anterior scalene) syndrome, which in most literature has been subsumed under the broader TOS diagnosis, was identified as early as 1935 by pain in the anterior or posterior aspect of the arm and at the upper medial border of the scapula, as well as by the tenderness of the muscle to palpation.^{9,26,38} In 1942, Travell et al²⁴ reported signs caused by scalene TrPs that included venous obstruction, vasomotor changes, and if the syndrome was severe, evidence of arterial insufficiency with compression of the motor and sensory nerves of the affected arm. The literature is clear that a scalene muscle problem is primarily responsible for neural or vascular entrapment in many patients who are commonly diagnosed as having TOS (refer to Chapter 33 for more clinical considerations).

Relief of pain by infiltrating the scalene muscles was used by Adson³⁹ as a diagnostic test to distinguish the scalenus anterior syndrome from structural causes of cephalobrachialgia. The TrP nature of the syndrome was not recognized. After an initial

wave of enthusiasm for scalenotomy following Adson's report, interest waned because emphasis shifted to carpal tunnel syndrome and radiculopathy from nerve root compression by a protruded cervical disc. Research continues to use botulinum toxin injection and anesthetic block of the scalenus anterior muscle diagnostically, for treatment, and predicting successful scalenotomy.^{40–43}

Braun et al investigated the effect of an anterior scalene muscle block (ASMB) on work production and time to fatigue in 34 individuals disabled with UE symptoms consistent with a diagnosis of TOS.⁴⁴ They studied work production and time to fatigue pre and post ASMB. They utilized three UE test positions: push pull at waist level and overhead and shoulder abduction to 90° with elbow flexion to 90° and repetitive hand gripping. All patients had improvement in power generation and time to fatigue post ASMB. The investigators conclude that the scalenus anterior muscle may hold the first rib in an elevated position and the ASMB allows a change in contour of the costoclavicular space and thoracic outlet. Therefore, if TrPs are present in the scalene muscles, they may have an effect on the first rib position and the contour of the costoclavicular space. While it has not been studied as such, this research indicates that injection of the scalenus anterior muscle provides relief for those with neurogenic TOS. This theory seems to suggest that scalenus anterior syndrome or neurogenic TOS may instead frequently be caused or perpetuated by scalene TrPs.

Many disciplines recognize the importance of diagnosing and treating TrPs in patients with symptoms of a TOS. An osteopathic physician⁴⁵ reported that in most cases of TOS, scalene or pectoral TrPs are responsible and treated them with myofascial release and self-stretching.⁴⁶ A physician practicing physical medicine and rehabilitation⁴⁷ noted that scalene TrPs commonly mimic the symptoms of a C6 radiculitis component of a TOS and that pectoralis minor TrPs create symptoms of medial cord compression. A physical therapist⁴⁸ identified TrPs in the scalene, supraspinatus, infraspinatus, and pectoral muscles as most commonly mimicking TOS. This topic is covered under the clinical considerations section in Chapter 33.

A C5-C6 radiculitis can produce pain very similar to that reported by patients with scalene TrPs. Cervical radiculitis in the C5 or C6 nerve roots often result in the formation of TrPs in those muscles innervated by the same nerve roots. Often patients with C5-C6 radicular symptoms report having deep anterior shoulder pain, anterolateral arm and forearm pain, and pain into the radial aspect of the hand and lateral two-and-a-half digits. Wainer et al²⁷ identified a test item cluster to determine the likelihood that a patient is presenting with cervical radicular symptoms. The following five predictor variables were identified: a positive Spurling sign, cervical rotation less than 60° to the same side, positive cervical compression test, relief of symptoms with axial distraction, and a positive neurodynamic upper limb test. Patients presenting with four of these positive variables have a 90% posttest probability of cervical radiculopathy. Patients with three positive variables have a 65% posttest probability of cervical radiculopathy.²⁷

Carpal tunnel syndrome may occur as a concurrent entrapment with TOS, or the symptoms of carpal tunnel syndrome may be caused by scalene TrPs. Loss of normal

mobility of the structures forming the carpal tunnel often contribute to the entrapment of the median nerve. Edema, reflexively originating from scalene TrPs, can be another important contributing factor.

Articular dysfunctions in C4, C5, and C6 are commonly associated with TrPs in the anterior and middle scalene muscles. Another articular dysfunction that is commonly observed with scalene muscle involvement is the elevation of the first and/or the second rib(s) (Figure 20-10). An apparent elevation of the first rib is typically concurrent with a T1 articular dysfunction.

Figure 20-10. Computed tomographic view of the thoracic outlet viewed from front with three-dimensional shaded surface display. The first rib at the costotransverse joint on the left side (long arrow above) is displaced upward compared with the asymptomatic right side. This displacement is associated with an abnormal position of the whole first rib (short white arrow at the bottom right of figure). Reproduced with permission from Lindgren KA, Manninen H, Rytkönen H. Thoracic outlet syndrome—a functional disturbance of the thoracic upper aperture? *Muscle Nerve*. 1995;18:526–530.

A tilted shoulder girdle axis, sometimes caused by the functional scoliosis associated with a leg length discrepancy and/or a small hemi-pelvis, places chronic strain on the

scalene muscles that should help straighten the tilted neck to level the eyes for good vision. An uncorrected leg length discrepancy or other frontal plane asymmetry as little as 1 cm (3/8th in), sometimes less, can perpetuate scalene TrPs despite all other efforts in management.¹³

5. CORRECTIVE ACTIONS

The patient should avoid habitual sustained or repetitive motions that overload the scalene muscles such as carrying awkward packages that require lifting with the arms extended out in front of the body and hauling, pulling, or tugging strenuously. Increasing intra-abdominal pressure by performing Valsalva during lifting or defecating should be avoided. Carrying a heavy backpack for prolonged periods of time, as well as sporting activities such as swimming, may lead to the formation of scalene TrPs and modifications to these behaviors may be necessary for full relief of symptoms and prevention of reoccurrence.

Correction of poor posture (particularly “rounded shoulder” posture with an excessive forward head position) and maintenance of good posture in sitting, standing, and sleeping are primary in any treatment approach both for initial relief of pain and for lasting relief. Refer to Chapter 76 for discussions of posture and body mechanics.

Utilizing progressive lenses during work-related activity that requires typing, reading, and writing might place the scalene muscles in a prolonged shortened position by moving the head from a balanced neutral position to a flexed position to perform the work task effectively.

For sleeping, the patient should use only one soft comfortable pillow of the right thickness to maintain a normal cervical lordosis. In a supine position, the proper thickness does not allow any extension of the head but also does not place the head in excessive flexion, as this causes prolonged shortening of the scalene and anterior neck muscles during sleep. A small towel roll can be placed inside the pillowcase to support the neck in a neutral position, thus placing the face parallel to the ceiling. The patient can tuck the corner of the pillow between the shoulder and chin in the side-lying position but not under both the head and the shoulder. During side-sleeping, the pillow should be thick enough to keep the head and neck in a neutral position so that the head is not bent excessively to either side because this causes excessive lengthening of the muscle on the top side and excessive shortening of the muscle on the pillow side. It is recommended to avoid sleeping prone due to the excessive rotation and extension placing the scalene muscles in a lengthened position. If one does sleep prone, a pillow placed under the shoulder and the chest on the same side to which the face is turned helps reduce rotation and extension of the neck. A semi-prone position can also be utilized, achieved by flexing the knee and the hip of the side toward which the face is turned, partly rotating the torso (Figure 7-5A to C).

If reading in bed, the light should be located directly overhead, on the headboard, on the wall, or suspended from the ceiling. It should not illuminate only one side of the bed because this placement can place excessive strain on the scalene muscles if the head is turned and tilted downward to maximize the light cast on the reading material.

When using a phone, it should not be held between the head and the shoulder. Instead, a headset, headphones, or hands-free speaker function should be utilized.

Correction of a posture is of paramount importance, as is the use of safe and efficient body mechanics for a long-term relief from muscle pain. Postural correction and body mechanics are discussed thoroughly in Chapter 76. Critical to recovery of patients with scalene TrPs is daily passive stretching of the scalene muscles at home. Stretching of the scalene muscles is illustrated in Figure 20-11A to D. With the patient lying supine, the shoulder of the side to be stretched (left side in this photo) is lowered and the hand anchored under the buttock (Figure 20-11A). The patient should learn to reach over the head to the ear with the hand of the contralateral side. They will assist the head and the neck to tilt it to the side away from the involved muscles while concentrating on relaxation of the neck muscles (Figure 20-11B). The head is drawn smoothly down toward the shoulder. The degree of head rotation determines which of the scalene muscles is specifically placed on stretch.

Figure 20-11. Self-stretch of the scalene muscles. A, Starting position. B, Posterior scalene. C, Middle scalene. D, Anterior scalene.

To stretch the scalenus posterior muscle (Figure 20-11B), the patient uses the assistive hand to gently pull the head and the neck into side-bending away from the side of the TrPs. They then turn the face away from the affected muscle. For the scalenus medius muscle, the patient looks straight up toward the ceiling (neutral position) or slightly toward the pulling arm (Figure 20-11C). To stretch the scalenus anterior muscle, the patient turns the face toward the affected muscle (Figure 20-11D). The patient concentrates the stretch on those directions in which the muscles feel tightest, holds each stretch for a slow count of 6 to 10 seconds while inhaling and slowly exhaling to give the stretched muscles time to release, and then gently taking up the slack. The head is then returned to the neutral mid-position. A pause, with deep diaphragmatic breathing between each passive stretch, helps reestablish complete muscular relaxation. The exercise should always be done bilaterally starting with the unaffected side. It may be more effective if performed after an application

of moist heat has warmed the skin over the scalene muscles for 10 to 15 minutes.

Lewit⁴⁹ describes and illustrates a gravity-assisted release of the scalene muscles that is particularly effective for the middle and posterior muscles with the patient side-lying and the TrP-involved muscle facing up. This technique of post-isometric relaxation is gentle, effective, and readily adapted to a self-stretch program for use at home. The patient is instructed to look upward and breathe in (contraction phase for scalene muscles in this position), hold the breath and the position about 6 seconds, then slowly breathe out, and let the head and the neck sink back to the table (relaxation phase of postisometric relaxation). This should be repeated 3 times. If breathing is faulty, the pattern should be corrected with training that establishes normal diaphragmatic breathing.

Coordinated respiration should be taught to those who are accustomed to using paradoxical breathing (chest breathing). Paradoxical respiration is a common source of overutilization and overload of the scalene muscles and is frequently adopted by patients following an abdominal surgery, chronic obstructive pulmonary disease, and by people who constantly retract a protruding abdomen to improve their appearance. Patients who breathe paradoxically should learn to synchronize diaphragmatic (abdominal) and chest breathing, if they are to relieve the scalene muscle overload (Figure 20-12A to C). Diaphragmatic breathing alone is most easily learned if the patient holds the chest fixed in the collapsed position rather than expanded (Figure 20-12B). Figure 20-12A to C depicts efficient diaphragmatic breathing pattern. Diaphragmatic breathing can also be performed in the seated position as depicted in Figure 20-13. For further information on instruction in diaphragmatic breathing see Chapter 76.

Figure 20-12. Diaphragmatic breathing. A, Starting in the hook-lying position. B, Top hand monitors the chest. When inhaling, the belly should protrude while the chest stays stationary. C, During exhalation through pursed lips, the belly flattens while the chest remains stationary.

Figure 20-13. Seated diaphragmatic breathing. A, Starting position. B, Inhalation with the belly protruding as the diaphragm contracts. C, Exhalation as diaphragm relaxes and abdominal muscles contract.

Trigger point pressure release, complemented by slow relaxed breathing, is another technique for inactivating scalene TrPs. To fully lengthen the scalene muscles, it is often necessary to treat parallel muscles in the neck that are also tense and restricting side-bending of the neck. Examples are the upper trapezius and the SCM muscle.

Supraspinatus Muscle

“Overhead Activity Archenemy”

Joseph M. Donnelly

1. INTRODUCTION

The supraspinatus muscle, a chief rotator cuff muscle, has three muscular heads and originates from the medial two-thirds of the supraspinous fossa of the scapula and the supraspinous fascia. It is thinner at the medial attachment, and becomes thicker as it travels laterally under the acromion to attach to the humerus. The three intertwined muscular heads give the muscle an increased ability to absorb tensile loads. The primary roles of this muscle are abduction and dynamic stability of the glenohumeral joint by compressive loading of the humeral head into the scapular glenoid fossa with the other rotator cuff musculature. It is considered to be the most active rotator cuff muscle and is involved with any functional activities that require the elevation of the upper extremity. Trigger points (TrPs) in the supraspinatus muscle produce a deep ache in the mid-deltoid region of the shoulder and can refer partway down the arm. It often refers pain to the lateral epicondyle of the humerus but rarely to the wrist. Symptoms may be exacerbated with sleeping on the affected side, carrying heavy objects with the arm hanging at the side, and reaching out to the side. Activation and perpetuation of TrPs in the supraspinatus muscle usually result from lifting objects to, or above, shoulder height with the arm outstretched or by performing tasks that demand repeated and/or moderately prolonged elevation of the arm. Differential diagnosis should include assessment for dysfunction of other rotator cuff and shoulder musculature, faulty scapulohumeral joint mobility, C5-C6 radicular symptoms, subdeltoid or subacromial bursitis, and scapular dyskinesia. Corrective actions include postural reeducation, effective sleep positioning, avoiding activities that overload the muscle, self-pressure release of TrPs, and self-stretch exercises.

2. ANATOMIC CONSIDERATIONS

The supraspinatus muscle originates from the medial two thirds of the supraspinous fossa

of the scapula and the supraspinous fascia.¹ The muscle is thinner at its most medial attachment and becomes thicker as it travels laterally to attach to the humerus. As the muscle courses laterally, the obliquely oriented anterior fibers converge with the more parallel posterior fibers of the muscle to form a thick tendon under the acromion that passes over the humeral head to insert on the superior facet of the greater tubercle of the humerus (Figure 21-1). The tendon is thicker at its anterior attachment and is continuous with the transverse humeral and coracohumeral ligaments.¹ The tendon is flatter at the attachment of the superior facet, and the deeper portion of the tendon blends with the glenohumeral joint capsule.¹ The supraspinatus tendon lies between the coracoacromial ligament anteriorly and the infraspinatus muscle posteriorly.

The supraspinatus muscle has been described as having three different muscular heads that give it the appearance of a braided rope.² Arising from the spine of the scapula, the posterior head travels anteriorly, while the middle head travels laterally, and the anterior head courses posteriorly. The thin posterior tendon overlaps the anterior and middle heads, intertwining all three heads, thus increasing the muscle's ability to mitigate tensile loading.² An aponeurotic expansion was identified in approximately 50% of 150 shoulders studied with magnetic resonance imaging (MRI). This aponeurotic expansion continues inferiorly from the supraspinatus tendon parallel to the long head of the biceps tendon in the bicipital groove, outside the synovial sheath, and inserts into the humerus at the superior aspect of the pectoralis major tendon.³

Deeper vertical fibers from the infraspinatus muscle conjoin with the supraspinatus tendon superiorly and cross the rotator cuff interval, extending anteriorly to the biceps brachii muscle. This thick fibrous tendon is referred to as the rotator cable,⁴ which links the posterior rotator cuff musculature to the anterior cuff muscle, and is commonly demonstrated in shoulder MRI scans.⁵ The rotator crescent is the distal arrangement of the tendon that consists of the insertion of the supraspinatus and infraspinatus tendons lateral to the rotator cable that inserts onto the humerus. The rotator cable is thought to protect the rotator crescent⁴ by transferring forces intrinsically from the posterosuperior rotator cuff to the anterior rotator cuff.¹ This complex insertion is thought to allow the rotator cuff to work in a coordinated fashion during all shoulder motions. Figure 21-1A identifies the attachments of the other three muscles that comprise the rotator cuff.

Figure 21-1. Attachments of the supraspinatus muscle (red). The other rotator cuff muscles are cut and reflected to show their attachments more clearly. A, Seen from above, including the relation of the humeral attachment of the supraspinatus muscle to the attachments of the other three rotator cuff muscles. B, Posterior view. If one envisions the trapezius attachments to the clavicle, the acromion, and the spine of the scapula, it becomes obvious how deep the muscle is due to the overlying trapezius muscle.

2.1. Innervation and Vascularization

The supraspinatus muscle is innervated by the suprascapular nerve through the upper trunk of the brachial plexus, primarily from the C5 to C6 spinal nerves,¹ and also from C4 in some individuals.⁶ The suprascapular nerve travels parallel with the clavicle and courses posteriorly through the suprascapular notch onto the supraspinous fossa to innervate the supraspinatus muscle. It abruptly changes its course around the spinoglenoid notch of the scapula, giving rise to motor branches that innervate the infraspinatus.⁶

The vascular supply to the supraspinatus muscle arises from the suprascapular and dorsal scapular arteries.¹ The suprascapular artery courses above the transverse scapular ligament; whereas the suprascapular nerve travels below the transverse scapular ligament in most cases.⁷

2.2. Function

The supraspinatus muscle is an important dynamic stabilizer of the glenohumeral joint along with the infraspinatus, teres minor, and subscapularis muscles. The supraspinatus muscle plays a key role in dynamic stability during shoulder abduction. The supraspinatus, middle deltoid, and middle trapezius muscles are activated prior to arm movement during abduction in the coronal plan, and the supraspinatus muscle achieves its peak of maximal volitional contraction (MVC) at 88° of abduction. The infraspinatus muscle achieves its peak MVC at 165° and the subscapularis muscle at 108° of abduction. The supraspinatus muscle appears to have a larger contribution to abduction earlier in the range of motion. The rotator cuff muscles are recruited early and increase throughout the range of motion contributing to coaptation of the humeral head in the glenoid.⁸ Kwon et al⁹ studied the cross-sectional area of the supraspinatus muscle at various degrees of glenohumeral abduction and found the largest cross-sectional area of this muscle to be between 60° and 90° of shoulder abduction, signifying its greatest activation in this range. This description is consistent with the findings from that of other researchers.⁸ Other authors have found that the pattern of activation in elevation in the coronal plane and plane of the scapula is similar in the supraspinatus, infraspinatus, and subscapularis muscles with all loads.^{10–12} There is a strong correlation of the activation of the supraspinatus muscle with that of the deltoid muscle, whereas the infraspinatus and subscapularis muscles' activation patterns are strongly correlated with those of axioscapular musculature.^{10,11} Witte et al¹³ reported similar findings; however, they conclude that the supraspinatus and deltoid muscles may

contribute to glenohumeral elevation moments in a complimentary manner. They also found that the response of the supraspinatus muscle to an increase in loading during multiple directions of shoulder elevation was highly variable as compared with the deltoid muscle which consistently increased activation with increased loading.¹³ The results of recent research do not support historical notions that the supraspinatus muscle is more effective than the deltoid muscle at initiation of abduction when the arm is at the side.

In an electromyographic (EMG) study, Basmajian and Deluca¹⁴ demonstrated that supraspinatus muscle activity alone, in the absence of other muscular activity at the shoulder, prevented downward displacement of the head of the humerus when the upper extremity, hanging at the side, was either loaded to exhaustion with a 7-kg weight or loaded with sudden downward jerks. This mechanism is effective because of the wedge action from the angulation of the glenoid fossa and the cartilaginous labrum.¹⁴

The EMG activity of the supraspinatus muscle during abduction of the arm increases almost linearly from resting to vigorous activity at 150° of abduction. During flexion, EMG activity increases rapidly at first, reaches a plateau, and increases again as flexion approaches 150°. ¹⁵ During sustained flexion or abduction to 90°, the supraspinatus muscle was the first to show evidence of fatigue compared with other shoulder muscles. After 5 minutes, both amplitude and frequency changes indicated advancing fatigue of the supraspinatus muscle.¹⁶ The common occurrence of supraspinatus tendinopathy in people who carry out work that requires arm elevation¹⁷ highlights the vulnerability of this muscle to overuse in this position.

During gait, the supraspinatus muscle is active during both the forward and backward arm swing (but not at the ends of the swing) to help prevent downward migration of the head of the humerus. During the golf swing in right-handed golfers, the right supraspinatus muscle starts out with moderate EMG activity (approximately 25% of manual muscle strength test) and progressively decreases to less than 10% of manual muscle strength test by late follow-through. The left muscle maintained relatively moderate EMG activity throughout the entire swing,¹⁸ with more activity during early and late follow-through. Jobe et al¹⁹ and Gowan et al²⁰ investigated muscle activation patterns and activity during throwing movements. They identified maximum activity of the supraspinatus, infraspinatus, and deltoid muscles during early and late cocking phases of the throw. They also identified that amateur sport players tend to utilize more of the rotator cuff muscles during the acceleration phase. Illyes et al²¹ investigated shoulder muscle activity during pushing, pulling, elevating, and throwing, and compared muscle activity in recreational athletes to that in professional overhead athletes. The supraspinatus muscle was found to have maximal activity during pulling, elevation, and fast overhead throwing. The time to peak activity was much higher and the duration of activity lasted longer in recreational athletes as compared with professional throwers. Their findings are consistent with those of Gowan et al,²⁰ who identified the deltoid, supraspinatus, and infraspinatus muscles as stabilizers and the subscapularis, pectoralis major, latissimus dorsi, and triceps brachii muscles as accelerators of the glenohumeral joint during throwing activities.²¹

Activation of the shoulder musculature has also been studied during different driving conditions. The supraspinatus and deltoid muscles were both found to have moderate to high muscle activation during driving (30%-50% MVC).²² If there is an injury or TrPs in one of these muscles, the other may not be able to compensate for the increased load as both muscles exhibit a high activation during normal driving conditions. Adjusting the driver's seat closer to the steering wheel so the shoulders can assume a resting position decreases average supraspinatus muscle activation by 45%.²²

Reinold et al^{23,24} investigated muscle activation in common rehabilitation exercises prescribed for the shoulder girdle. They found no statistical difference in supraspinatus muscle activation during any of the exercises tested. The "full can" exercise produced significantly less activity in the deltoid muscle; therefore, they conclude that this may be the best position to target the supraspinatus muscle for strength testing and exercises. High supraspinatus muscle activation was also demonstrated with standing external rotation with the arm abducted to 90°, prone external rotation with the arm at 90° abduction, and prone horizontal abduction at 100° with full external rotation. They also suggest using the "empty can" test to assess the rotator cuff's efficacy in preventing superior migration of the humeral head secondary to the high deltoid activation in this position.²⁴

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in the muscles that are functionally interdependent. Box 21-1 grossly represents the functional unit of the supraspinatus muscle.²⁵

Box 21-1 Supraspinatus muscle

Action	Synergists	Antagonists
Shoulder elevation (abduction)	Deltoid	Teres major Pectoralis major Latissimus dorsi Coracobrachialis Long head triceps brachii

The supraspinatus muscle also functions synergistically with the infraspinatus, teres minor, and subscapularis muscles to stabilize the head of the humerus in the glenoid fossa

during arm movements.^{10, 14}

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The referred pain pattern from TrPs in the supraspinatus muscle causes a deep ache of the shoulder, concentrating in the mid-deltoid region. The tenderness and pain that it projects to the mid-deltoid region can be easily mistaken for subdeltoid bursitis. This ache often refers down the arm and the forearm, and sometimes focuses strongly over the lateral epicondyle of the elbow (Figure 21-2).²⁶ This epicondylar component helps distinguish supraspinatus TrPs from infraspinatus TrPs, which do not typically refer concentrated pain to the elbow.^{26, 27} Occasionally, pain from supraspinatus TrPs is also referred to the wrist.

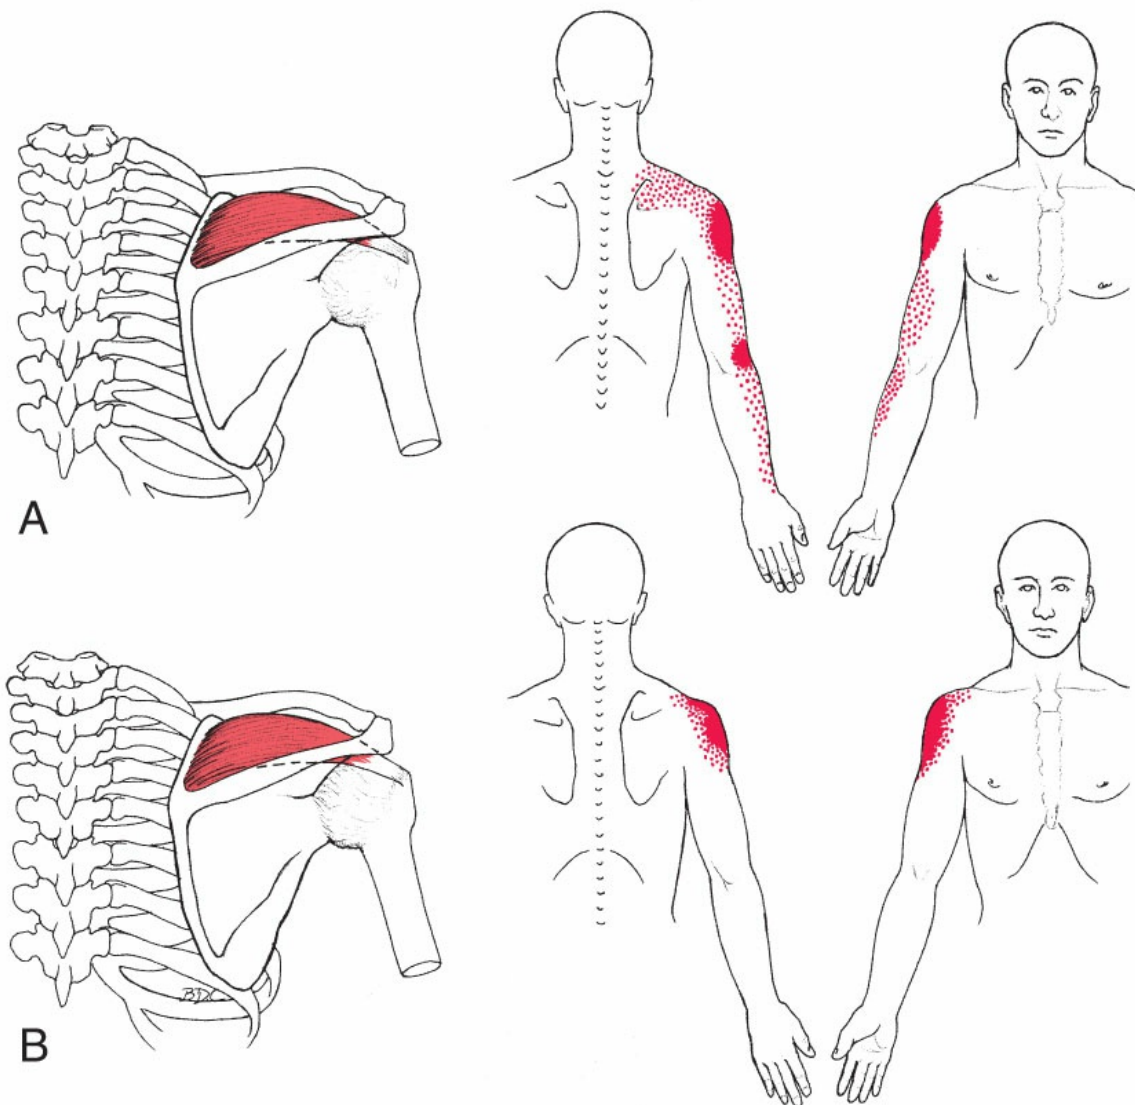

Figure 21-2. A and B, Referred pain patterns (essential reference zone solid red, spillover zone stippled red) of TrPs in the supraspinatus muscle. A, Trigger points may be located in any region of the muscle. B, In addition, a tender area located in the region of attachment of

the supraspinatus tendon to the capsule of the glenohumeral joint may be indicative of an enthesopathy.

Other authors have described the pain referred from the supraspinatus muscle as traveling toward (or into) the shoulder,^{28–30} to the outer side of the arm,^{28,31} and from the scapula to the mid-humerus.²⁹

Experimental injection of 6% hypertonic saline into normal supraspinatus muscles caused referred pain to the shoulder (three subjects), to the upper back (two subjects), and to the elbow (one subject).³²

3.2. Symptoms

The rotator cuff muscles are commonly implicated in patients who report shoulder pain with the supraspinatus muscle being one of the most frequently involved muscles.³³ Active TrPs in the supraspinatus muscle were found in 38% of individuals with nonspecific shoulder pain³⁴ and 65% of patients with a medical diagnosis of shoulder impingement.³⁵ Patients with supraspinatus TrPs often describe intense pain in the lateral aspect of the shoulder over the deltoid region with pain that may spread as far distally to the lateral epicondyle and forearm (Figure 21-2). The pain is usually felt intensely during the elevation of the arm at the glenohumeral joint, especially on initiation of the movement. Patients may experience a deep ache in the lateral aspect of the shoulder at rest that may mimic the pain of bursitis.³⁶ Pain usually prevents the patients from getting their arm above their head causing activity limitations. When the supraspinatus muscle on the dominant side is affected, the patients commonly report difficulty in reaching the head to comb their hair, brush teeth, or shave facial hair. Patients also report difficulty during sports activities that require arm elevation, such as serving in tennis. Patients with supraspinatus TrPs on the nondominant side may be unaware of even moderate restriction of these motions if the dominant arm usually performs these overhead activities. Ohmori et al³⁷ found that active TrPs in the supraspinatus and infraspinatus muscles were associated with shoulder pain during ipsilateral upper-extremity elevation in patients receiving a muscle-sparing thoracotomy; thus evaluation of shoulder muscles after surgical procedures that may require prolonged or unusual arm positioning is imperative for optimal postoperative recovery.

Supraspinatus TrPs alone rarely cause severe, sleep-disturbing nocturnal pain. Other authors have observed stiffness of the shoulder and nighttime ache secondary to the involvement of the supraspinatus muscle.²⁹ In patients older than 65 who report having nocturnal pain that disturbs sleep, examination for a rotator cuff tear should be performed. In some cases, if the supraspinatus TrP is highly irritable, the patient may report increased shoulder pain while walking due to supraspinatus activation during arm swing. In individuals who have recurrent lateral elbow pain or epicondylagia, the supraspinatus muscle should be examined. Some patients may report snapping or clicking sounds around the shoulder joint that is resolved when the supraspinatus TrPs are inactivated.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For a proper examination of the supraspinatus muscle, the clinician should observe the shoulder girdle posture, note the scapular position, and examine the active and passive ranges of motion of the shoulder girdle, paying special attention to muscle activation patterns and the scapulohumeral rhythm. The clinician should observe when and where the pain occurs. Supraspinatus TrPs can produce pain at rest or during movement particularly during arm elevation in any plane. The pain usually occurs throughout the abduction range of motion. If pain occurs only in one small arc of motion, evaluate for a rotator cuff injury. Clinically, this muscle is seldom involved in isolation. This muscle is commonly involved in association with the infraspinatus, deltoid, or the upper trapezius muscles that can also have TrPs.

To identify the range of motion deficits, and thus biomechanical dysfunction, that may be caused by TrPs in the supraspinatus muscle, the clinician should identify the limited range of motion by performing a specific range of motion testing for the supraspinatus muscle. Muscle-specific resisted testing should be carried out to identify impairments in muscle function and reproduction of painful symptoms. If active TrPs are present in the supraspinatus muscle, resisted elevation in the plane of the scapula is painfully inhibited.

The Apley's scratch test (shoulder extension, medial rotation, and adduction) can be used to identify restriction due to TrPs in the supraspinatus muscle. This version of the Apley's scratch test requires full adduction and medial rotation of the arm at the glenohumeral joint. It is performed by placing the hand of the affected side behind the back and reaching as far up toward the opposite scapula as possible. The fingertips should reach the inferior angle of the scapula (Figure 21-3A). This test also stretches the shoulder abductors and the infraspinatus muscle. When the range of these muscles is limited due to TrPs, the fingers may barely reach the hip pocket or thoracolumbar region. The limitation from supraspinatus TrPs is similar to when the movement is performed actively or passively. Conversely, TrPs in the antagonistic subscapularis muscle may allow the fingers to reach the spinal column, or farther, if done passively without contracting the subscapularis muscle in the shortened position.

Figure 21-3. A, Apley's scratch test (extension, medial rotation, and adduction) to put the shoulder abductors and lateral rotators on stretch and to shorten the shoulder adductors and medial rotators. B, Apley's scratch test (flexion, lateral rotation, and abduction) to put the shoulder adductors and medial rotators on stretch and to shorten the shoulder abductors and lateral rotators.

The other version of the Apley's scratch test (shoulder flexion, lateral rotation, and abduction) is typically restricted by supraspinatus TrPs (Figure 21-3B). In the upright position, the patient is unable to hold the arm fully abducted due to pain because this contracts the supraspinatus muscle in the shortened position and compresses any present enthesopathy at its humeral attachment. When in a supine position, the patient with supraspinatus TrPs has less difficulty performing the overhead Apley's scratch test because the muscle does not lift the weight of the arm.

Accessory joint motion should be tested in the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic joints. Often, joint hypomobility in the sternoclavicular joint can cause impairment in shoulder elevation that contributes to alterations in normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns, contributing to overload of the supraspinatus and other rotator cuff muscles.

Scapular and humeral head positions should be assessed at rest and during upper extremity elevation because malalignment can be a significant contributing factor to supraspinatus muscle overload during all upper extremity functional activities. The elbow complex should be included in the examination because the supraspinatus muscle often refers pain to that region.

Patients with supraspinatus TrPs may be aware of, and be concerned about, clicking in the shoulder during movement. The clicking can be heard and palpated when the patient moves the arm at the glenohumeral joint in a way that incriminates the involved fibers of the supraspinatus muscle. Inactivating the supraspinatus TrPs eliminates the symptoms. The mechanism of this clicking is unknown but may relate to enthesopathy because the palpable source is also tender, or it may be associated with the inhibition of the supraspinatus muscle.

The humeral attachment of the supraspinatus tendon is most easily palpated if the hand of the upper limb being examined is placed behind the back at the waist level with the arm medially rotated. This position brings the tendon within the reach from beneath the acromion. Palpation often reveals a marked tenderness beneath the deltoid at the attachment of the supraspinatus tendon.

3.4. Trigger Point Examination

The patient sits comfortably, or lies on the uninvolved side, with the affected arm close to the body and is relaxed. In the case of less active TrPs, it may be desirable to place the arm behind the back, putting the supraspinatus muscle on stretch. The supraspinatus muscle should be palpated through the trapezius muscle utilizing cross-fiber flat palpation. The muscle should be palpated along its entire length within the supraspinous fossa to identify TrPs (Figure 21-4). Trigger points are typically located in the supraspinous fossa of the scapula underneath a relatively thick part of the trapezius muscle. Therefore, a local twitch response of the supraspinatus muscle is unreliably elicited by cross-fiber flat palpation and is not always perceived by needle penetration. Tenderness to palpation is often elicited in the mid-region of the supraspinous fossa (the midportion of some fibers pass here at about half the thickness of the muscle) but can be elicited anywhere in the supraspinous fossa because supraspinatus fibers attach throughout the medial two thirds of the fossa. The presence of spot tenderness in the lateral region, between the spine of the scapula and the clavicle, just medial to the acromion, most likely represents involvement of the musculotendinous junction secondary to increased muscle tension associated with the overuse of the supraspinatus muscle.

Figure 21-4. Cross-fiber flat palpation for TrPs in the supraspinatus muscle. The arrow depicts palpation direction.

The severity and the extent of the referred pain evoked by needling TrPs in the muscular area are usually out of proportion to the slight degree of tenderness due to deep palpation reported by the patient, probably because of the depth of the muscle that should be penetrated diffuses the specificity of manual palpation pressure.

The tendinous attachment into the head of the humerus, where the tendon of the muscle blends with the joint capsule to form part of the rotator cuff under the acromion, can be also be tender to palpation (Figure 21-2B). This tender region corresponds to the poorly vascularized area described by Hagberg¹⁷ that is particularly vulnerable to sustained or repeated overload.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the supraspinatus muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³⁸ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Supraspinatus TrPs can be activated by carrying heavy objects such as a suitcase, briefcase, or package with the arm hanging down at the side, or by regularly walking a large dog that pulls on a leash. Trigger points in this muscle can also be activated by lifting an object to, or above, shoulder height with the arm outstretched or by performing tasks that demand repeated and/or moderately prolonged elevation of the arms.¹⁷

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by other TrPs,³⁹ therefore, musculature in the referred pain areas for each muscle should also be considered. Release of the TrP in the muscle often allows for an immediate decrease in the pressure pain threshold of the associated TrPs.³⁹ This relationship is most commonly observed when TrPs in the supraspinatus muscle cause associated TrPs in the deltoid, lateral head of the triceps, and anconeus muscles.

Unlike the referred pain from the infraspinatus TrPs, which go deep into the shoulder and are easily mistaken for the arthritis of the glenohumeral joint,⁴⁰ the shoulder pain from supraspinatus TrPs lacks a deep, aching quality.

Clinical experience suggests that the supraspinatus, infraspinatus, deltoid, and biceps brachii muscles frequently develop TrPs at the same time and that the trapezius muscle may become involved as part of the functional unit. This notion is supported by recent research studies that investigated the prevalence and treatment of TrPs in patients presenting with shoulder pain.^{41–43}

4.3. Associated Pathology

Cervical radiculitis in the C5 or C6 nerve roots often result in the formation of TrPs in those muscles innervated by the same nerve roots. Often patients with C5-C6 radicular symptoms report deep anterior shoulder pain, anterolateral shoulder pain, brachium and forearm pain, and pain into the radial aspect of the hand and the lateral two-and-a-half digits. Wainner et al⁴⁴ identified a test item cluster to determine the likelihood that a patient is presenting with a cervical radiculopathy. The following five predictor variables were identified: a positive spurling sign, cervical rotation less than 60° to the same side, positive cervical compression test, relief of symptoms with axial distraction, and a positive neurodynamic upper limb test. Patients presenting with four of these positive variables have a 90% posttest probability of cervical radiculopathy. Patients with three positive variables have a 65% posttest probability of cervical radiculopathy.⁴⁴

Other diagnoses to consider include cervical arthritis or spurs with nerve root irritation and brachial plexus injuries. These neurogenic sources of pain are likely to exhibit EMG evidence of denervation (positive sharp waves and fibrillation potentials) in the muscles supplied by the compromised nerves. Muscles with TrPs show no EMG evidence of denervation because EMG evidence of muscle entrapment of a nerve would present in the muscles that are distal to the muscle causing the entrapment.

Shoulder pain accounts for approximately 12% of musculoskeletal conditions, and subacromial impingement syndrome (SIS) is the most prevalent diagnosis.⁴⁵ The direct cost for the treatment of shoulder pain in the United States was estimated to be \$7 billion in the year 2000.⁴⁶ In a systematic review of the evidence related to the diagnosis of impingement syndrome of the shoulder by Papadonikolakis et al,⁴⁷ they concluded that the original diagnosis of impingement syndrome was developed to cover the breadth of rotator cuff

disorders including tendinosis and complete and incomplete tears that were difficult to differentiate. These authors suggest that we drop the impingement syndrome diagnosis due to recent advancements in the diagnostics that allow differentiation of these diagnoses.⁴⁷ Diercks et al⁴⁸ suggested a guideline for the diagnosis and treatment of subacromial pain syndrome that includes the examination and treatment of TrPs. This syndrome is further discussed in Chapter 33 under Clinical Considerations.

Investigators have looked at the prevalence of TrPs, pressure pain threshold (PPT), and reproduction of shoulder pain in patients with nonspecific shoulder pain⁴⁹ or the diagnosis of impingement syndrome.^{35, 43} Hidalgo-Lozano et al³⁵ assessed 12 patients and 10 matched controls for the prevalence of TrPs and PPT. The inclusion criteria were: pain greater than 3-month duration, pain greater than 4/10 with shoulder elevation, and positive Neer and Hawkin's impingement tests. Patients with SIS had a greater number of active and latent TrPs. The highest prevalence of active TrPs was noted in the supraspinatus (62%), infraspinatus (42%), and subscapularis (42%) muscles. Patients with SIS demonstrated a decreased PPT that directly correlated with the number of TrPs. Each patient with SIS had up to three active TrPs. The greater the number of TrPs present, the lower the PPT. The results of their study lend credence to the idea that both peripheral and central pain mechanisms are present in patients with SIS. Manual treatment of these TrPs reduced shoulder pain and pressure sensitivity in individuals with SIS.⁵⁰ Similarly, the presence of TrPs in 10 muscles was investigated in 27 patients with a diagnosis of SIS and 20 matched controls.⁴³ The number of muscles with TrPs was significantly greater in the SIS group as compared with the control group, with the infraspinatus, subscapularis, and trapezius muscles having a significant number of active and latent TrPs. The infraspinatus muscle had the highest prevalence of active TrPs in the SIS group. The greater prevalence of TrPs in the SIS group signals the significance of myofascial pain in the presentation of SIS. Interestingly, TrPs in the supraspinatus muscle were found bilaterally in patients with SIS. Therefore, bilateral examination is important in patients with a diagnosis of SIS.⁴³

In patients with unilateral shoulder pain and a diagnosis of SIS with associated positive impingement tests, it is essential to examine neck and shoulder muscles bilaterally for the presence of both active and latent TrPs. In addition to supraspinatus TrPs, subdeltoid bursitis, subacromial bursitis, adhesive capsulitis, and rotator cuff pathology may all cause tenderness at the tendinous attachment to the rotator cuff (capsule) beneath the acromion. Only TrPs, however, cause spot tenderness in the muscle belly of the supraspinatus muscle. Bursitis, adhesive capsulitis, and rotator cuff pathology are discussed in greater detail in Chapter 33 under Clinical Considerations.

Suprascapular nerve entrapment is a relatively rare entrapment seen in athletes performing repetitive cocking motions.⁵¹ The cocking position requires shoulder abduction, extension, and external rotation, followed by rapid flexion and internal rotation.¹⁹ Suprascapular nerve injury has also been identified in older individuals with degenerative changes in the glenohumeral joint and with capsular laxity associated with the aging process. This nerve entrapment is typically caused by repetitive overhead sports

activity, ganglion cysts, or scapular fractures. Areas of entrapment include the suprascapular notch under the superior transverse ligament and the spinoglenoid notch in the presence of a space-occupying lesion.⁵² Diagnosis by nerve conduction and EMG of both the infraspinatus and supraspinatus muscles is required to make this diagnosis. If the patient does not respond to rest and other conservative measures, surgery is indicated. A patient with suprascapular nerve entrapment reports vague shoulder girdle pain and demonstrates atrophy over the supraspinatus and infraspinatus muscles, limited shoulder range of motion, and fatigue in the shoulder girdle.⁵² The patient's reports of pain may be similar to those caused by TrPs in shoulder girdle musculature especially the supraspinatus and infraspinatus muscles.

Scapulohumeral muscle imbalances, more commonly referred to as scapular dyskinesia, is defined as an alteration of normal motor recruitment pattern of muscle contraction of the shoulder girdle musculature during upper extremity movements. This alteration of normal muscle recruitment can lead to poor coordination, early fatigue, and overloading of the rotator cuff muscles. The role of scapular dyskinesia in myofascial pain and dysfunction is described in Chapter 33 under Clinical Considerations.

For patients with shoulder pain whose symptoms do not match their diagnosis or who have failed to improve with other conservative measures, supraspinatus TrP diagnosis and treatment can be invaluable.

5. CORRECTIVE ACTIONS

The patient with supraspinatus TrPs should avoid habitual, sustained, or repetitive motions that overload the supraspinatus muscle. This includes refraining from carrying heavy objects in the hand of the affected shoulder with the arm hanging down at the side, reaching backward or out to the side to retrieve objects, and lifting heavy items overhead. The patient should also avoid sustained contraction of the muscle, as when maintaining the arm in an elevated position (eg, holding the arms up continuously for several minutes to style hair or to work overhead). Occasionally, lowering the arms to relax the muscles can replenish their blood supply and prevent TrP formation.

When the patient lies on the uninvolved side, sleep is improved by supporting the uppermost elbow and forearm (painful limb) on a bed pillow, as described in Figure 22-4, to avoid the "watershed position" (Figure 22-4), which places undue tensile stress on the supraspinatus muscle. Another option is to place the pillow under the arm, perpendicular to the body so that the arm is out of the adducted position, thereby eliminating the supraspinatus muscle from being kept under tension. Patients should be cautioned regarding lying in bed with their arm(s) above their head in an abducted and externally rotated position because this position keeps the supraspinatus and infraspinatus muscles in a prolonged shortened position, causing increased tension.

The patient may inactivate supraspinatus TrPs using a TrP pressure release tool (Figure 21-5). This treatment is most comfortable if the pressure is applied while the involved arm is relaxed and supported in a comfortably adducted position. A more aggressive approach of

this release involves taking up slack in the muscle (while TrP pressure release is continued) by sliding the hand behind the back, activating the antagonists to the supraspinatus muscle and thereby, allowing it to relax through reciprocal inhibition. A cold pack may be of therapeutic benefit post pressure release, especially in the case of acute shoulder pain.

Figure 21-5. Trigger point self-pressure release of the supraspinatus muscle.

The patient can stretch the supraspinatus muscle by slowly and firmly pulling the forearm behind the back in an upward direction with the other hand to position the involved arm as in Figure 21-6A. This passive stretch may be performed most effectively under a warm shower with the water beating on the muscle.

Figure 21-6. A, Self-stretch of the supraspinatus muscle. B, Self-stretch of supraspinatus and infraspinatus muscles if position A is unattainable due to pain.

If both supraspinatus and infraspinatus TrPs are extremely sensitive and the patient has difficulty placing the hand behind the back, the arm may be brought across the front of the chest instead (Figure 21-6B). An effective self-stretch technique is the application of post-isometric relaxation (progressive contract-relax) with respiratory augmentation. The patient stretches the muscle by bringing the elbow of the involved side across the front of the chest with the other hand to take up slack in the muscle. As the patient takes slow deep breaths and during exhalation relaxes the muscle, the arm is brought further across the body passively with the unaffected arm. Lewit⁵³ illustrates this across-chest position and describes patient application of post-isometric relaxation that can be very helpful.

When prescribing neuromuscular reeducation or therapeutic exercises for the supraspinatus muscle, activation is greater with standing elevation in the plane of the scapula with thumbs up (full can), thumbs down (empty can), and in prone horizontal abduction 100° with full external rotation (full can).²⁴ Decker et al⁵⁴ found the greatest activity of the infraspinatus (115% MVC) and supraspinatus (125% MVC) muscles during the push-up plus activity. To minimize muscle activation of the supraspinatus and infraspinatus muscles, other authors suggest utilizing supported vertical and diagonal wall slides.^{55, 56}

Posterior glenohumeral joint tightness, when present, must be addressed to restore efficient shoulder girdle mechanics while concomitantly treating TrPs in the supraspinatus muscle. Treatment solely focused on TrPs in the supraspinatus muscle, which does not address the shoulder joint, results in treatment failure and only temporary relief of pain arising from TrPs in the supraspinatus muscle.

Infraspinatus Muscle

“Side-Sleeper’s Nemesis”

Joseph M. Donnelly

1. INTRODUCTION

The infraspinatus muscle is a thick, irregularly shaped muscle, consisting of three muscle bellies: superior, middle, and inferior. The muscle originates from the medial two-thirds of the infraspinous fossa below the spine of the scapula and the adjacent fascia from the lower fibers of the trapezius, rhomboids, and serratus anterior muscles. The infraspinatus muscle inserts onto the middle facet on the posterior aspect of the greater tuberosity of the humerus. The infraspinatus muscle is innervated by the suprascapular nerve. The irregular shape and morphology of the infraspinatus muscle allow it to be a major contributor to glenohumeral joint stability, providing force to seat the humeral head in the glenoid of the scapula during upper extremity movement. Its chief action is external rotation of the shoulder along with the teres minor muscle. Trigger points (TrPs) in the infraspinatus muscle produce shoulder joint pain deep in the anterior deltoid region and are distally referred into the lateral forearm and radial aspect of the hand. Pain may be referred to the medial scapular border, to the suboccipital region, and occasionally to the posterior cervical region. Symptoms may be exacerbated with sleeping on the affected side, reaching behind the back, and performing activities of daily living that require combined movements of shoulder elevation and external rotation. Activation and perpetuation of TrPs in the infraspinatus muscle usually result from acute overload while reaching backward and upward or with overhead lifting with the upper extremity in external rotation. Differential diagnosis should include assessment for posterior glenohumeral joint capsule tightness, neurodynamic testing to rule out neural pathomechanics, C5-C6 radiculitis, bicipital tendonitis, and suprascapular nerve entrapment. Corrective actions should include postural reeducation (including proper sleep position), elimination of positions that cause recurrent overload on the muscle, self-pressure release of TrPs, and self-stretch exercises.

2. ANATOMIC CONSIDERATIONS

The infraspinatus muscle is contained within the infraspinatus fascia which is described as a tough sheet of connective tissue, that covers the infraspinous fossa and envelopes the infraspinatus muscle. Muscle fibers originate from both the fascia and the fossa.¹ The infraspinatus muscle originates from the medial two thirds of the infraspinous fossa below the spine of the scapula and the adjacent fascia from the lower fibers of the trapezius, rhomboids, and serratus anterior muscles. A fascial connection has also been identified between the posterior deltoid and infraspinatus muscles.¹ The infraspinatus inserts onto the middle facet on the posterior aspect of the greater tuberosity of the humerus² (Figure 22-1). The tendon may blend superiorly and posteriorly with the shoulder joint capsule³ and can be separated by a small bursa.² The infraspinatus tendon fuses with the supraspinatus tendon just lateral to the spine of the scapula.² Investigators utilizing cadaver specimens demonstrated the gross anatomic structure of the infraspinatus muscle as being comprised of three distinct muscle partitions (heads).⁴ These partitions were described as the superior, the middle, and the inferior partitions. The fibers of the superior partition are horizontally aligned, whereas the fibers of the middle and inferior partitions are oriented superolateral and terminate into the central thickened tendon. The middle partition of the muscle has a distinct fibrous band that inserts deep to the superior and inferior partitions and is thought to attach to the middle and superior facet with the supraspinatus muscle.² The deeper fibers pass at acute angles to conjoin with the supraspinatus muscle superiorly and cross the rotator cuff interval, attaching to the subscapularis tendon. This thick fibrous tendon is referred to as the rotator cable⁵ that links the posterior rotator cuff muscles to the anterior cuff muscle. Lateral to the rotator cable, the distal arrangement of the tendon that inserts onto the humerus is called the rotator crescent. It consists of the distal insertions of the infraspinatus and supraspinatus tendons. The rotator cable is thought to protect the rotator crescent⁵ by transferring forces intrinsically from the posterosuperior rotator cuff to the anterior rotator cuff.² This complex insertion allows the rotator cuff to work in a coordinated fashion during all the shoulder motions.

Figure 22-1. Infraspinatus muscle attachments from the medial two thirds of the infraspinous fossa to the middle facet on the posterior aspect of the greater tuberosity of the humerus. Deeper fibers attach to the superior facet conjoining with fibers of the supraspinatus to form the rotator cable.

2.1. Innervation and Vascularization

The infraspinatus muscle is innervated by the suprascapular nerve that is derived from the upper trunk of the brachial plexus and the primary ventral rami of C5 and C6, with C5 contributing the majority of fibers.^{6,7} The suprascapular nerve passes dorsolaterally through

the posterior triangle of the neck and under the superior transverse scapular ligament into the supraspinous fossa. In the supraspinous fossa, the nerve provides innervation to the supraspinatus muscle before coursing laterally through the spinoglenoid notch to enter the infraspinous fossa. In the infraspinous fossa, primary, secondary, and tertiary branches provide innervation to the infraspinatus muscle. In more than 60% of specimens evaluated, the three partitions of the infraspinatus muscle were all innervated by a first-order branch of the suprascapular nerve.⁴ The suprascapular nerve is subject to compression and potential entrapment as it passes under the transverse scapular ligament and in the spinoglenoid notch.^{8,9}

The vascular supply to the infraspinatus muscle is provided by the suprascapular and circumflex scapular arteries.²

2.2. Function

The infraspinatus, teres minor, supraspinatus, and subscapularis muscles insert into the greater and lesser tuberosities of the humerus to form a musculotendinous rotator cuff. These rotator cuff muscles provide dynamic stability to the glenohumeral joint. Motion at the shoulder is a complex coordinated activity, and the moment arms of the rotator cuff muscles exert inferiorly and medially directed forces that resist upward shear of the deltoid muscle during shoulder elevation while keeping the head of the humerus in close contact with the glenoid fossa.¹⁰ The primary function of the infraspinatus muscle, along with the other three rotator cuff muscles, is to stabilize and center the head of the humerus in the glenoid fossa with any upper extremity movement. It also serves as a passive restraint to posterior subluxation and as a dynamic restraint against anterior subluxation of the head of the humerus.¹¹ The infraspinatus muscle has a primary action of external rotation at the glenohumeral joint, with the arm in any position.^{12–14}

Some authors have reported the infraspinatus muscle as having a moderate maximum voluntary contraction (% MVC) in standing and side-lying external rotation movements; whereas peak activity was noted with prone horizontal abduction between 90° and 100° with full external rotation.^{13,14} More recent research demonstrated that the infraspinatus muscle is active prior to humeral movement during shoulder flexion,¹⁵ elevation in the plane of the scapula, and abduction in the coronal plane, and it reaches peak intensity at 165° of abduction.^{10,14,16,17} Investigators theorize that the infraspinatus muscle has a role in counterbalancing the deltoid and pectoralis major muscles during shoulder elevation in addition to externally rotating the humerus to achieve full elevation. In abduction, multiple muscles contribute both to the abductive force and to the stabilization of the humeral head in the glenoid fossa.

Electromyographical studies have demonstrated that infraspinatus muscle activity increased linearly with increasing abduction, with additional peaks of activity during flexion.^{17,18} The maximum isometric rotation moment capacity was greater at 0° abduction compared with 90° abduction.¹⁴ Because of the superior belly's horizontal arrangement, it may be primarily responsible for the action of external rotation in neutral to 10°.¹⁹

The infraspinatus muscle serves as one of the primary decelerators of the throwing arm^{18,20-22} and the follow-through arm in a golf swing.²³ The deceleration function, which requires an eccentric contraction, may be a contributing factor to the formation of TrPs^{24,25} and breakdown on the undersurface of the infraspinatus tendon.²⁰ In throwers, near the moment of ball release, there is a large distraction force between the glenoid cavity and the humerus during this deceleration phase. The large distraction force is resisted by a strong eccentric contraction of the infraspinatus muscle, placing it at risk for tensile overload.²⁶ Other investigators found that the infraspinatus muscle is maximally activated during a fast overhead throw and moderately active during pushing and pulling activities.²⁷

Basmajian and Deluca²⁸ described how the angulation of the glenoid fossa, together with the activity of horizontal fibers in several muscles, provides a coaptation force that prevents downward displacement of the head of the humerus. They showed that the activity of the supraspinatus muscle and the posterior fibers of the deltoid muscle prevented downward displacement of the humeral head, even with considerable downward loading of the adducted arm. In other positions, however, additional protection of the joint by rotator cuff muscular activity, which includes contraction of the infraspinatus muscle, becomes critical.²⁸

Functionally, as the position of the arm changes, the function of the shoulder girdle muscles also change. The infraspinatus muscle is best aligned at 100° of scaption to exert an active compressive force between the humeral head and the glenoid along with combined motions of external rotation and horizontal abduction. This position may be optimal for resistance exercises of the infraspinatus muscle.^{13,14}

Reed et al¹⁶ found that as an external load increased during abduction in the plane of the scapula, the activity levels in the infraspinatus muscle increased systematically. The muscle activation pattern established with low loads is maintained as the load increases. They conclude that this activation pattern supports the law of proportional activation against the law of minimal activation based on activation of muscles with the least synergistic activity. Lucas et al²⁹ reported similar findings; however, they observed increased infraspinatus muscle activity level and early activation with an external load and presence of TrPs in the scapular upward rotators.²⁹

The infraspinatus muscle's level of activity increases significantly with turning a car wheel, and to a much lesser extent, when the wheel is centered.³⁰ The highest level of activation noted in the infraspinatus muscle is following a steering maneuver when the wheel is being placed back to the center position. When the steering wheel is held in the center position, there is a cocontraction of shoulder muscles to stabilize the wheel.³⁰

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a

TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 22-1 grossly represents the functional unit of the infraspinatus muscle.²⁴

Box 22-1 Functional unit in the infraspinatus muscle

Action	Synergists	Antagonists
Shoulder lateral rotation	Teres minor Posterior deltoid	Subscapularis Pectoralis major Latissimus dorsi Anterior deltoid

In addition, the infraspinatus muscle functions synergistically with the teres minor, the supraspinatus, and the subscapularis muscles to stabilize the head of the humerus in the glenoid fossa during arm movements.^{10, 28}

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the infraspinatus muscle refer pain deep in the anterior aspect of the shoulder.³¹ Most reports of the referred pain pattern from the infraspinatus identify the anterior aspect of the shoulder as the major target area (Figure 22-2).^{31–36} In 193 cases of referred pain from the infraspinatus muscle, all patients identified the anterior aspect of the shoulder as painful.³³ The pain was described as also projecting down the anterolateral aspect of the arm,^{31, 33–37} to the lateral forearm,^{31, 33–36} to the radial aspect of the hand,^{31, 33–37} and occasionally to the fingers^{33, 37} or to the upper posterior cervical region and medial border of the scapula (Figure 22-2). Patients usually identify the most painful area by covering the front of the shoulder with their hand.

Figure 22-2. Referred pain patterns (red) in the right infraspinatus muscle. Solid red shows essential referred pain zones, stippled red areas show spillover zones.

Trigger points in the infraspinatus muscle have also been found to refer pain to the posterior aspect of the shoulder; however, this pain may result from TrPs simultaneously present in the adjacent teres minor muscle.²⁴ Bonica and Sola³⁸ described aching pain referring primarily to the region of the deltoid muscle. Rachlin³⁹ emphasized pain to the posterior aspect of the shoulder and also included referral along the medial border of the scapula as well as to the base of the neck in the region of the levator scapulae muscle.

Much of the variation among these reports is probably due to the appearance of referred pain in the variable spillover zones. Among 193 subjects with infraspinatus TrPs, 6% experienced pain in the deltoid and the biceps brachii regions, none reported elbow pain, 21% reported pain in the radial forearm, 13% in the radial side of the hand, and 14%

in the suboccipital posterior cervical area.³³ No distinction was made in the pain patterns arising from these TrPs.

One patient with an aberrant pain pattern of infraspinatus TrPs was described. In that case, the pain was referred superficially to the front part of the chest. After the initial injection, the patient returned with the expected infraspinatus pain pattern that resolved with additional injections of infraspinatus TrPs.⁴⁰

Experimentally, pressure stimulation of an active infraspinatus TrP increased alpha motor neuron excitability in the anterior fibers of the deltoid that in turn induced a referred pain pattern to the anterior aspect of the shoulder. Motor unit activity appeared at rest in the deltoid muscle during referred pain elicited by the application of digital pressure. The patient was unable to eliminate the motor unit activity by relaxation, although surrounding muscles not within the pain reference zone were electrically silent. This finding supports recent evidence that TrPs can refer increased alpha motor neuron excitability as well as pain. Fernández-Carnero et al⁴¹ showed that an increased nociceptive activity in latent TrPs in the infraspinatus muscle might increase motor activity and sensitivity of a TrP in distant muscles, eg, the extensor carpi radialis brevis muscle, at the same segmental level.

Referred pain from the infraspinatus muscle was induced experimentally by injecting the normal muscle with 6% hypertonic saline. Deep pain was felt at the tip of the shoulder, in the posterior and lateral aspects of the shoulder, and in the anterolateral aspect of the arm.⁴²

3.2. Symptoms

Trigger points in the infraspinatus muscle typically cause shoulder pain at rest, interfering with functional activities and sleep. Patients may report a deep ache in the anterior aspect of the shoulder and often describe the pain as being “deep in the joint.” The pain can spread down the anterolateral aspect of the arm, the lateral forearm, the radial side of the hand, and occasionally into the fingers. The patient’s symptoms may be similar to those of C5-C6 radicular pain or carpal tunnel syndrome. One study observed that approximately one third of patients referred with a clinical suspicion of carpal tunnel syndrome but with negative EMG findings had TrPs in the infraspinatus muscle.⁴³ In fact, Hains et al⁴⁴ observed that TrP therapy using ischemic compression was a useful approach to reduce symptoms associated with the carpal tunnel syndrome. Patients may also report pain along the medial border of the scapula over the insertion of the rhomboid muscles, significant activity limitations, and participation restrictions due to TrPs in the infraspinatus muscle.

When the patient’s chief report is pain in the anterior aspect of the shoulder, infraspinatus, supraspinatus, deltoid (anterior and middle), biceps brachii, coracobrachialis, scaleni, pectoralis major and minor, and subclavius muscles are the most likely muscular sources of symptoms.⁴⁵ In fact, active TrPs in the infraspinatus muscle can contribute to symptoms in patients with mechanical neck pain,⁴⁶ women with postmastectomy pain,⁴⁷ desk or industrial workers,⁴⁸ or individuals with medical diagnosis of subacromial

impingement syndrome.⁴⁹ A thorough examination for the presence of TrPs in the shoulder girdle musculature is essential to improve patient functional outcomes for shoulder pain.^{50,51}

Common reports of pain in patients with TrPs in the infraspinatus muscle are presented in Box 22-2. Sola and Williams⁵² identified the symptoms of shoulder girdle fatigue, weakness of grip, loss of mobility at the shoulder, and hyperhidrosis in the referred pain area as due to TrP activity in the infraspinatus muscle.

Box 22-2 Common reports from patients with active TrPs in the infraspinatus

I can't reach into my back pants pocket.
I can't fasten my brassiere behind my back.
I have to put this arm into my coat sleeve first.
I can't reach into the back seat of my car.
I have difficulty combing or brushing my hair.
Brushing my teeth is painful.
I can't play overhead sports.

The patient with TrPs in the infraspinatus muscle may also report increased local and/or referred pain at night due to sleeping postures and spontaneous activation of active TrPs (Figure 22-2). The weight of the thorax compresses and stimulates the infraspinatus TrPs while the patient is lying on the painful side (and sometimes on the back).³¹ This hypothesis is supported by Ohmori et al⁵³ who reported that active TrPs in the supraspinatus and infraspinatus muscles are associated with shoulder pain in patients receiving muscle-sparing thoracotomy. The authors suggested that the position of the shoulder against the table was one of the main factors for activation of infraspinatus TrPs.⁵³ When the patient lies on the pain-free side for relief, the uppermost arm is likely to fall forward causing a painful stretch of the affected infraspinatus muscle, again disturbing sleep. Thus, patients with active infraspinatus TrPs may find that they can sleep only by propping themselves up while seated in a reclined position for the night.

A major part of the shoulder girdle pain associated with hemiplegia is commonly due to TrPs in the trapezius, levator scapulae, supraspinatus, infraspinatus, subscapularis, deltoid, and rhomboids muscles. In the absence of spasticity at rest, TrPs in these muscles usually respond well to local treatment.⁵⁴ These authors found that all patients after stroke who were randomly assigned to the dry needling group (n = 54) plus standard rehabilitation, exhibited infraspinatus TrPs in addition to TrPs in other shoulder girdle muscles. Following an intervention with dry needling, the patients reported restoration of sleep, significant decrease in frequency and intensity of pain during the day, and less pain and discomfort during rehabilitation as compared with those in the control group receiving standard rehabilitation only.⁵⁴

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper examination of the infraspinatus muscle, the examiner should observe the shoulder girdle posture, active and passive ranges of motion of the shoulder girdle, muscle activation patterns, and the scapulohumeral rhythm. Investigators have found that the presence of TrPs in the infraspinatus muscle can cause an inconsistent muscle activation pattern during shoulder elevation,⁵⁵ and that the infraspinatus muscle fires first and consistently in the presence of latent TrPs in the scapular upward rotators.²⁹ To identify TrPs in the infraspinatus muscle that may be limiting the range of motion and thus influencing dysfunction, the clinician should identify the limited range of motion by performing specific range of motion tests for all parts of the infraspinatus muscle. In addition to examination of passive medial rotation in neutral, the examiner should also include horizontal adduction as the superior belly of the infraspinatus muscle is lengthened with this motion, often reproducing the patient's pain. Muscle-specific resisted testing should be performed to identify impairments in muscle function and reproduction of painful symptoms. If active TrPs are present in the infraspinatus muscle, resisted lateral rotation in the neutral position is painfully inhibited.

The Apley's scratch test (extension, adduction, and medial rotation) can be used to identify restriction in the infraspinatus muscle due to TrPs. The hand-to-shoulder-blade test requires full adduction and medial rotation of the arm at the glenohumeral joint. This test is performed by placing the hand of the affected side behind the back and reaching as far up toward the opposite scapula as possible. The fingertips should reach the inferior angle of the scapula (Figure 21-3 in Chapter 21). This test stretches the shoulder abductors and the infraspinatus muscle. When the range of these muscles is limited due to TrPs, the fingers may barely reach to the hip pocket or thoracolumbar region. Range of motion limitation is similar when the movement is performed actively or passively. Conversely, TrPs in the antagonistic subscapularis muscle may allow the fingers to reach the spinal column, or farther, if done passively without contracting the subscapularis muscle in the shortened position, while an active limitation of this same motion is evident.

Accessory joint motion should be tested in the glenohumeral joint, acromioclavicular joint, sternoclavicular joint, and scapulothoracic joints. Many times, joint hypomobility in the sternoclavicular joint can cause impairment in shoulder elevation, contributing to alterations in the normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns, contributing to overload of the infraspinatus and other rotator cuff muscles.

The glenohumeral joint should be carefully assessed for Glenohumeral Internal Rotation Deficit, which may be indicative of posterior capsule tightness. Scapular position and humeral head position should also be assessed at rest and during upper extremity elevation, as malalignment can be a significant contributing factor to infraspinatus muscle

overload during all upper extremity functional activities.

3.4. Trigger Point Examination

Trigger points in the infraspinatus muscle are common in patients who report shoulder pain. The prevalence of active infraspinatus TrPs in patients with nontraumatic chronic shoulder pain is significant. In a study of 72 subjects with chronic shoulder pain, the most affected muscle was the infraspinatus muscle, which demonstrated active TrPs in 77% of subjects.⁴⁵ This study reinforces the findings from Ge et al⁵⁶ who commonly reported active TrPs patients with unilateral shoulder pain. Infraspinatus TrPs have also been associated with whiplash-associated disorders,⁴⁶ chronic work-related shoulder and neck complaints,⁴⁸ women with postmastectomy pain,⁴⁷ or shoulder impingement syndrome.⁴⁹ It is not uncommon to find multiple TrPs, both active and latent, in the infraspinatus muscles of patients with shoulder pain.⁵⁶

In a study of 126 patients, investigators found referred pain to the shoulder region arose from the infraspinatus muscle in 31% of the cases, a frequency second only to that of the levator scapulae muscle (55%).³⁴ In an unpublished research project, Donnelly found that the prevalence of latent TrPs in 92 healthy pain-free adults was 70% in the infraspinatus muscle, as compared with 13% in the biceps brachii and 27% in the triceps brachii muscles.

The infraspinatus muscle may be examined for TrPs with the patient seated, side-lying on the pain-free side, or in prone. When the patient is seated, the arm may be supported by the side of the body (Figure 22-3). Cross-fiber flat palpation frequently reveal multiple taut bands containing TrPs in this muscle.^{45,56} Trigger points are typically found in the midportion (endplate zone) of the infraspinatus muscle; however, the entire muscle needs to be palpated for an accurate diagnosis. Ge et al⁵⁶ investigated topographical mapping and pain pressure threshold (PPT) of TrPs in the infraspinatus muscles in 21 female patients with primary reports of unilateral shoulder pain. They found multiple active TrPs on the painful side but not on the uninvolved side. They also found multiple latent TrPs both on the painful side and uninvolved side. A majority of the active and latent TrPs were found to be located in the mid-fiber region of the infraspinatus muscle.⁵⁶ Occasionally, a TrP may cause pain referral to the medial border of the scapula and adjacent rhomboid muscles (Figure 22-2).

Figure 22-3. Cross-fiber flat palpation for TrPs in the infraspinatus muscle. A, Superior fibers. B, Middle fibers. C, Inferior fibers.

Each of the three distinct muscle partitions (superior, middle, and inferior) should be examined carefully. Knowledge of fiber direction is critical, as cross-fiber flat palpation should be performed along the length of the entire infraspinatus muscle to locate the taut bands and identify spot tenderness within the taut band.

Firm bands in this superficial muscle may be more difficult to identify than one might expect. Local twitch responses (LTRs) are moderately difficult to elicit by cross-fiber flat snapping palpation. The overlying skin is often thick and indurated by associated panniculosis. Referred pain can usually be evoked or aggravated by sustained pressure on an infraspinatus TrP. Trigger points in the infraspinatus muscle typically have a referred pain latency when pressure is applied to the TrP, which can take up to 30 seconds for distal referral of symptoms.

In a study by Bron et al,⁵⁷ the interrater reliability of palpation of TrPs in three shoulder muscles (infraspinatus, biceps brachii, and deltoid) was investigated in asymptomatic subjects, patients with unilateral shoulder pain, and patients with bilateral shoulder pain.⁵⁷ They found that experienced clinicians had a greater than 70% agreement in identifying TrPs in the infraspinatus muscle. They also found that referred pain was the most reliable feature in all muscles, whereas identification of the taut band, LTR, and jump sign were the most reliable criteria for identifying TrPs in the infraspinatus muscle. Their findings were also consistent with those of Ge et al⁵⁶ who identified latent TrPs bilaterally in those patients presenting with unilateral shoulder pain and a more frequent location of

TrPs in the mid-fiber region of the muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the infraspinatus muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁵ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. Infraspinatus TrPs are usually activated by an acute overload or by repeated overload, such as the stress of frequently reaching to the back seat of a car, reaching back from an office chair, grabbing behind for support to regain balance (eg, grasping the railing when slipping on stairs), twisting the arm that holds a ski pole during a fall, delivering an especially hard tennis serve when off balance, or with dragging a novice ice skater around by the arm for a long period of time. Vigorous weight training with heavy overhead loads or eccentric loading can also precipitate the formation of TrPs in the infraspinatus muscle. The onset of shoulder pain is usually within a few hours of the initiating trauma. The patient can generally identify when the muscle was overloaded.

Baker⁵⁸ found that between 20% and 30% of the infraspinatus muscles of patients experiencing their first motor vehicle accident had active TrPs following the accident, regardless of the direction of impact. This was slightly lesser than the number of TrPs that developed in the supraspinatus muscles of these patients.

Bron et al⁵¹ investigated the role of TrPs in chronic shoulder pain and dysfunction. Patients were randomly assigned to either a treatment group or a control group. The control group was placed on a waiting list (wait and see) for 12 weeks. The number of active TrPs present was less in the intervention group at 12 weeks as compared with the control group; however, there was no difference in the number of latent TrPs. Active TrPs in the infraspinatus and other rotator cuff musculature were responsible for reproduction of the patients pain. There was a positive correlation in the number of active TrPs and the score on the Disability of Arm, Shoulder, and Hand (DASH) that demonstrated a change of 24% as active TrPs were inactivated. They reported a 55% improvement in pain and function in the intervention group with a significant reduction in the number of active TrPs at 12 weeks.⁵¹

Hidalgo-Lozano et al⁵⁹ investigated the prevalence and mechanical sensitivity of several shoulder and neck muscles in elite swimmers with and without shoulder pain. They demonstrated that elite swimmers with shoulder pain had significantly decreased PPT as compared with that in controls. However, swimmers without shoulder pain showed no significant difference in PPT as compared with those with shoulder pain. Swimmers with shoulder pain had a significant number of active TrPs present in the infraspinatus and subscapularis muscles, which on palpation reproduced the swimmers pain. Surprisingly, they found active TrPs in swimmers without shoulder pain as well. When the swimmers

were questioned about this finding, they reported that it was a historically familiar pain. Both elite swimmers with and without shoulder pain had a significant number of latent TrPs; however, the latter had a higher prevalence.⁵⁹

Repetitive overuse is also seen in competitive overhead athletes. The overhead volleyball or tennis serve can cause repetitive strain and TrP formation in the rotator cuff muscles especially the infraspinatus muscle. Osborne et al⁶⁰ identified TrPs in volleyball players that developed after several long days of training and tournament play. Release of the TrPs restored an active range of motion and allowed the athletes to quickly return to competitive play.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.⁶¹ Therefore, musculature in the referred pain areas for each muscle should also be considered. Three groups of muscles develop TrPs in association with the infraspinatus muscle. Any given patient typically exhibits involvement of one of the three groups. The first group consists of the anterior deltoid muscle, which lies in the essential pain reference zone of the infraspinatus muscle, and the biceps brachii muscle, which may also become involved with prolonged activation of the infraspinatus muscle. The second group includes the teres major and latissimus dorsi muscles. The third group includes the subscapularis and pectoralis major muscles, which are antagonistic to the infraspinatus muscle in lateral rotation of the humerus.

Other muscles that can refer pain to the same region as the infraspinatus muscle are the upper, middle, and lower trapezius; supraspinatus; scalene; teres minor; middle deltoid; triceps brachii; and pectoralis minor muscles. All these muscles should be examined for the presence of TrPs, especially when resolution of the patient's shoulder pain is not being achieved with the treatment of TrPs in the infraspinatus muscle.

4.3. Associated Pathology

Cervical radiculitis in the C5 or C6 nerve roots often result in the formation of TrPs in those muscles innervated by the same nerve roots. Often patients with a C5 or C6 radiculopathy report having deep anterior shoulder pain, anterolateral arm and forearm pain, and pain into the radial aspect of the hand and lateral two-and-a-half digits. Wainner et al⁶² identified a test item cluster to determine the likelihood that a patient is presenting with a cervical radiculopathy. The following predictor variables were identified: a positive Spurling sign, cervical rotation less than 60° to the same side, positive cervical compression test, relief of symptoms with axial distraction, and a positive neurodynamic upper limb test. Patients presenting with four of these positive variables have a 90% posttest probability of cervical radiculopathy. Patients with three positive variables have a 65% posttest probability of cervical radiculopathy.⁶²

Often times, it is clinically seen that patients who are administered postoral steroid or epidural spinal injection for cervical radicular symptoms have residual pain in the upper

extremity that is often related to TrP activity in the infraspinatus muscle. Treatment of infraspinatus TrPs can alleviate the remaining upper extremity pain in this type of patient.

Shoulder pain accounts for approximately 12% of musculoskeletal conditions, with subacromial impingement syndrome being the most prevalent diagnosis.⁶³ The direct cost for the treatment of shoulder pain to the United States was estimated to be \$7 billion in the year 2000.⁶⁴ In a systematic review of the evidence related to the diagnosis of impingement syndrome of the shoulder, Papadonikolakis et al⁶⁵ concluded that the original diagnosis of shoulder impingement syndrome was developed to cover the breadth of rotator cuff disorders including tendinosis, as well as complete and incomplete tears that were difficult to differentiate. They suggest that the impingement syndrome diagnosis no longer be utilized due to recent advancements in diagnostics that allow these diagnoses to be differentiated.⁶⁵ Diercks et al⁶⁶ suggested a guideline for the diagnosis and treatment of subacromial pain syndrome, that includes clinical examination and treatment of TrPs.

As discussed in Chapter 21, authors have investigated the prevalence of TrPs, PPT, and reproduction of shoulder pain in patients with a diagnosis of impingement syndrome.^{49, 67} The greatest prevalence of active TrPs was noted in the supraspinatus (62%), the infraspinatus (42%), and the subscapularis (42%) muscles. This study clearly supports that the number of active TrPs in the shoulder musculature was related to increased pressure pain sensitivity in individuals with “shoulder impingement syndrome.”⁴⁹ This association suggests that active TrPs in the infraspinatus muscle could be associated with sensitization mechanisms in patients with shoulder pain. This hypothesis is also confirmed by the association of both active and latent TrPs in the infraspinatus muscle with lower PPT⁵⁶ and the presence of bilateral TrPs in the infraspinatus muscle in patients with unilateral shoulder symptoms.⁶⁷

Because the infraspinatus muscle is one of the rotator cuff muscles, differential diagnosis should rule out rotator cuff dysfunction. With rotator cuff dysfunction, the pain is severe and is usually exhibited through a limited arc of motion. It has been identified as a test item cluster of signs and symptoms indicative of rotator cuff pathology. The variables identified were age, supraspinatus weakness, weakness in external rotation, and impingement. Any two positive variables in combination with age more than 60 was associated with a posttest probability of 98% and at any age with three positive variables was associated with a 98% posttest probability. Any two positive variables with age less than 60 was associated with a 64% posttest probability of rotator cuff pathology.⁶⁸

Suprascapular nerve entrapment is a relatively rare entrapment seen in athletes performing repetitive cocking motions. The cocking position requires abduction, extension, and external rotation followed by rapid flexion and internal rotation.²¹ Suprascapular nerve injury has also been identified in individuals with degenerative changes in the glenohumeral joint and with capsular laxity in an aging population. Entrapment is typically caused by repetitive overhead activity in overhead athletes, by ganglion cysts, or by scapular fractures. Areas of entrapment include the suprascapular notch under the superior transverse ligament or at the spinoglenoid notch secondary to a space-occupying lesion.⁶⁹ Diagnosis by nerve

conduction and electromyography of both the infraspinatus and supraspinatus muscles is required to make this diagnosis. If the patient does not respond to rest and other conservative measures, surgery is indicated. Typical signs and symptoms include a vague report of shoulder girdle pain, atrophy over the supraspinatus and infraspinatus muscles, limited shoulder range of motion, and fatigue in the shoulder girdle.⁶⁹ The patient's pain may be similar to that caused by TrPs in the shoulder girdle musculature, especially the supraspinatus and infraspinatus muscles.

5. CORRECTIVE ACTIONS

The patient with infraspinatus TrPs should avoid habitual sustained or repetitive motions that overload the muscle, such as repetitive overhead lifting with the upper extremity in abduction and external rotation and reaching backward into the back seat of the car.

When the patient lies on the uninvolved side, sleep is improved by supporting the uppermost elbow and forearm (painful limb) on a bed pillow (Figure 22-4A) to avoid overstretching the affected infraspinatus muscle that can cause referred pain. For back sleepers, a pillow may be placed between the arm and the trunk, so that the pillow rests under the arm to keep the shoulder in a relaxed position (Figure 22-4B). A neutral sleeping posture is best. Patients should be cautioned regarding lying in bed with their arm(s) above their head in an abducted and externally rotated position, as this will keep the infraspinatus muscle in a prolonged shortened position causing increased tension in the TrP region. When seated, a pillow may be used in the same manner to place the shoulder in a resting position (Figure 22-4C).

Figure 22-4. Pain-relieving positions for active right infraspinatus TrPs. A, Side-lying position of relief is with the affected side up with arm in slight abduction, passively placing the infraspinatus muscle in a resting position. B, Supine position of relief is with the arm supported in slight abduction. Note the right arm is not allowed to fall behind the body due to the support of the pillow. C, Seated position of relief is with the affected arm supported in slight abduction, neutral rotation by a pillow.

When prescribing neuromuscular reeducation or therapeutic exercises for the infraspinatus muscle, activation is greater with standing external rotation with the arm at the side (44% MVC), and in side-lying (42% MVC). Utilizing a towel roll in the axilla during external rotation activates the posterior deltoid muscle to assist the infraspinatus muscle with external rotation.¹² Decker et al⁷⁰ found the greatest activity of the infraspinatus (115% MVC) and supraspinatus (125% MVC) muscles during the push-up plus activity.

The patient may inactivate an infraspinatus TrP with self-pressure release of TrPs by lying on a tennis ball placed directly under a tender spot in the muscle or standing with their back against the wall utilizing the aforementioned technique. Body weight is used to maintain increasing pressure for 1 to 2 minutes, as described in the interventions section. The self-pressure release of TrPs may be repeated several times daily until the TrP is inactivated. A cold pack may be of therapeutic benefit post pressure release, especially in the

case of acute shoulder pain. There are a variety of commercialized products that can be used for pressure release techniques.

The patient may stretch the muscle daily while seated or while taking a warm shower. To stretch all three heads of the muscle, the arm first be stretched across the chest in front, then up the back from behind (Figure 22-5A and B).

Figure 22-5. Stretch positions for the infraspinatus muscle. A, To stretch the superior belly, the affected shoulder is placed in maximum horizontal adduction at 90° of shoulder elevation with overpressure supplied by the unaffected extremity. B, To stretch the middle and inferior bellies, the affected arm is placed behind the patient's back in extension, medial rotation, and adduction. A towel is used to allow the unaffected arm to passively pull the affected arm into more medial rotation stretching the infraspinatus muscle. The stretch can be augmented with a contract-relax or postisometric relaxation technique.

Another effective self-stretch technique is the application of post-isometric relaxation (progressive contract-relax) with respiratory augmentation. The patient lies supine with the affected upper limb placed such that the elbow extends over the edge of the bed or sofa with the elbow flexed 90° (Figure 22-6A).⁷¹⁻⁷³ The patient inhales slowly and deeply and then relaxes during exhalation, while gravity assists the arm in slowly falling downward to stretch the infraspinatus muscle (Figure 22-6B). Additional release of infraspinatus muscle tightness may be achieved by a voluntary effort to lower the hand (medially rotate the arm), providing additional stretch within a comfortable range.

Figure 22-6. Postisometric relaxation for the infraspinatus muscle. A, Starting position. B, Stretch position.

In cases of glenohumeral posterior capsule tightness, it is imperative that the connective tissue dysfunction be addressed in addition to restoration of scapulohumeral mechanics while concomitantly treating TrPs in the infraspinatus muscle. Treatment isolated to TrPs in the infraspinatus muscle that does not address the arthrokinematics of the scapulohumeral joints results in a treatment failure and only a temporary relief of pain.

Teres Minor Muscle

“Throwers Trial”

Joseph M. Donnelly

1. INTRODUCTION

The small, slightly fusiform teres minor muscle is one of the four rotator cuff muscles of the shoulder. It attaches from the posterior aspect of the scapula to the inferior facet of the greater tubercle of the humerus, and it acts to dynamically stabilize the humeral head in the glenoid fossa of the scapula and to laterally rotate the arm at the glenohumeral joint. Trigger points (TrPs) in the teres minor muscle produce pain deep in the posterior deltoid region of the shoulder, near its insertion on the humerus. Symptoms may be exacerbated by sleeping on the affected side, reaching behind the back, and performing activities of daily living that require combined movements of shoulder elevation and external rotation (ER). Activation and perpetuation of TrPs in the teres minor muscle usually result from acute overload while reaching backward and upward, or with repetitive overhead activities. Differential diagnosis should include assessment for posterior glenohumeral joint capsule tightness, rotator cuff tears, quadrilateral space syndrome, and C8-T1 radicular symptoms. Corrective actions include postural training (including effective sleep positioning), behavior change to eliminate positions that cause recurrent overload on the muscle, self-pressure release, and self-stretch exercises.

2. ANATOMIC CONSIDERATIONS

The teres minor muscle originates medially from the upper two thirds of the flattened area of the dorsal surface of the scapula that roughly extends from the medial aspect of the inferior angle to the posterior and the inferior aspects of the glenoid fossa of the scapula and from the aponeurosis that separates this muscle from the infraspinatus and teres major muscles that border it superiorly and inferiorly, respectively. It inserts lateral to the inferior facet of the greater tubercle of the humerus and onto the humerus, proximal to the origin of the lateral head of the triceps brachii muscle (Figure 23-1). The tendon blends with the

lower posterior aspect of the glenohumeral joint capsule. In some cases, the teres minor muscle may fuse with the infraspinatus muscle.¹ Two distinct fascial variations have been reported: the teres minor muscle may be contained in its own inflexible facial compartment or it may share the facial compartment of the infraspinatus muscle.²

Figure 23-1. Attachments of the teres minor muscle showing location and direction of muscle fibers.

2.1. Innervation and Vascularization

The teres minor muscle is innervated by the axillary nerve through the posterior cord from the C5 and C6 spinal segments. This innervation differs from that of the infraspinatus

muscle above, which is supplied by the suprascapular nerve, and from that of the teres major muscle below, supplied by the lower subscapular nerve. All three muscles are supplied at least in part from the cervical spinal segments C5 and C6.¹

Loukas et al³ investigated the course of the axillary nerve in 100 nerve specimens. In 65% of the cases, the axillary nerve split within the quadrangular space into an anterior and a posterior branch. The remaining 35% split within the deltoid muscle. Irrespective of the origin, the posterior deltoid branch gave off a branch to the teres minor muscle in 100% of the cases.^{3,4}

The teres minor muscle receives its vascular supply through the posterior humeral circumflex and circumflex scapular arteries.¹

2.2. Function

The teres minor, infraspinatus, supraspinatus, and subscapularis muscles insert into the greater and lesser tuberosities of the humerus and form a musculotendinous rotator cuff. These rotator cuff muscles provide dynamic stability to the glenohumeral joint. Motion at the shoulder is a complex, coordinated activity performed by the rotator cuff muscles, which exert inferior and medially directed forces that resist upward shear forces of the deltoid muscle during shoulder elevation while keeping the head of the humerus in a close contact with the glenoid fossa.⁵ The teres minor muscle functions with the other rotator cuff muscles to stabilize and center the head of the humerus in the glenoid with upper extremity movement.

Apart from its stabilizing role, the teres minor (along with the infraspinatus) muscle is a prime mover at the glenohumeral joint for ER with the arm in any position.^{6,7} The teres minor muscle has a moderate maximal volitional contraction (%MVC) in standing and side-lying ER movements.⁷ Peak activity for the teres minor muscle is with prone horizontal abduction at 90° of abduction and full ER with the elbow extended. The teres minor muscle demonstrates the least activity during ER in the plane of the scapula and with a towel roll in the axilla.⁶ The teres minor muscle activation patterns mirror those of the infraspinatus muscle with both muscles having greater than a 40% MVC during six of seven motions studied.⁶

Investigators have utilized positron emission tomography to look at the function of the teres minor muscle in shoulder adduction (0°) and abduction positions (90° in the frontal plane) on healthy volunteers. Their results showed that the teres minor muscle had a more definitive role in ER in the abducted position.⁸

Although weak adduction has been identified as an action of the teres minor muscle on the basis of anatomic orientation,¹ there is no electromyographic evidence to date to support adduction as a function of this muscle.^{5-7,9,10} However, a weak adduction function may be extrapolated from the teres minor muscle's role in dynamic stabilization of the glenohumeral joint by providing a medial and inferiorly directed force during shoulder elevation.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. The teres minor muscle functions in parallel with the infraspinatus muscle, to which it is a “little brother,” having similar attachments but a different nerve supply. Box 23-1 grossly represents the functional unit of the teres minor muscle.¹¹ The teres minor muscle also functions synergistically with the infraspinatus, supraspinatus, and subscapularis muscles to stabilize the head of the humerus in the glenoid fossa during arm movements.^{5,9}

Box 23-1 Functional unit of the teres minor muscle

Action	Synergists	Antagonists
Shoulder external rotation	Infraspinatus Posterior deltoid	Subscapularis Pectoralis major Latissimus dorsi Anterior deltoid

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the teres minor muscle primarily refer deep pain in the region of the posterior deltoid muscle toward the insertion of the teres minor muscle (Figure 23-2). This area of pain lies proximal to the deltoid muscle’s attachment at the deltoid tubercle of the humerus. It can be concentrated in a small area (about the size of a prune) well below the subacromial bursa but could feel like “bursitis” because of its sharp localization and deep quality. A broadly distributed aching pain in the arm and the shoulder posteriorly is rarely due to TrPs in the teres minor muscle alone. Bonica and Sola¹² illustrate a broader distribution of pain in the region of the posterior deltoid muscle.

One report of four patients¹³ indicates that referred dysesthesia of tingling and numbness to the fourth and fifth fingers may be as common as pain referred to the shoulder by active TrPs in the teres minor muscle.

Figure 23-2. Referred pain pattern (essential zone solid red, spillover zone stippled red) of TrPs in the right teres minor muscle.

3.2. Symptoms

Compared with other rotator cuff muscles, the teres minor muscle is less commonly involved in primary shoulder pain despite active TrPs being found in 45% of individuals with nonspecific shoulder pain.¹⁴ A patient with teres minor TrPs may earn a diagnosis of “painful bursa” due to the report of pain deep in the posterior deltoid muscle close to the attachment of the teres minor muscle on the humerus. The patient’s primary concern is typically posterior shoulder pain rather (Figure 23-2) than restricted shoulder range of motion (ROM). Clinically, teres minor TrPs occur concomitantly with infraspinatus TrPs. When the patient presents with pain deep in the anterior shoulder, the symptom is likely due to active TrPs in the infraspinatus muscle rather than the teres minor muscle. When pain from infraspinatus TrPs is relieved and normal infraspinatus muscle length is restored, the patient may become aware of the pain in the back of the shoulder referred by the teres minor muscle.

Escobar and Ballesteros¹³ reported four patients with isolated active teres minor TrPs.

All four described symptoms of numbness and/or tingling of the fourth and fifth fingers aggravated by shoulder activity that required reaching above the shoulder height or behind them. These movements also caused pain in three of the patients. In a more recent case report, a patient with posterior shoulder tightness was successfully treated after application of dry needling to the teres minor and infraspinatus muscles.¹⁴ Pain and restricted ROM of the shoulder improved after dry needling of these muscles restored more normative sensory and motor function.¹⁵

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper examination of the teres minor muscle, the clinician should observe the shoulder girdle posture, examine active and passive ranges of the motion of the shoulder girdle, and observe muscle activation patterns as well as the scapulohumeral rhythm.

The teres minor muscle has been considered one of the less commonly involved shoulder muscles. About 7% of patients with myofascial pain in the shoulder region were found to have TrPs in the teres minor muscle in earlier studies.^{16,17} Only 3% of healthy young adults had latent TrPs in the teres minor or teres major muscles.¹⁶ Bron et al¹⁴ investigated the prevalence of TrPs in nontraumatic unilateral chronic shoulder pain and found a high prevalence of active TrPs in the teres minor (45%) muscle. They also found a high prevalence of latent TrPs (20%) in the teres minor muscle. The authors recommend examination for the presence of TrPs in patients who present with shoulder pain.¹⁴

Usually, the patient presents with primary TrPs in the infraspinatus muscle. Active TrPs in the teres minor muscle may show some restricted ROM in the Apley's scratch test (see Figure 22-3) even after TrPs in the infraspinatus muscle have been inactivated by treatment. When the pain report shifts from the front of the shoulder (in the case of infraspinatus TrPs) to the back of the shoulder (pain distribution of teres minor TrPs), assessment of TrPs in the teres minor muscle is indicated.

Accessory joint motion should be tested in the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic joints. Often, joint hypomobility in the sternoclavicular joint can cause impairment in shoulder elevation, which contributes to alterations in the normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns contributing to overload of the teres minor and other rotator cuff muscles.

The glenohumeral joint should be carefully assessed for Glenohumeral Internal Rotation Deficit, which may be indicative of posterior capsule tightness. A recent case report suggests that TrPs in the teres minor muscle can be involved in posterior shoulder tightness.¹⁵ Scapular position and humeral head position should be assessed at rest and during upper extremity elevation as malalignment can be a significant contributing factor

to teres minor muscle overload during all upper extremity functional activities.

3.4. Trigger Point Examination

Several positions may be useful when examining a patient for teres minor TrPs. One option is for the patient to assume a prone position with the arm in 90° of abduction supported on the table and the elbow bent to 90° with the forearm hanging from the table's edge (Figure 23-3A). This position may be useful to allow for ease of glenohumeral internal and ER ROM testing to help differentiate between the teres major and the teres minor muscles. The teres minor muscle can be identified by palpating the muscle while the patient alternately attempts internal and external rotation of the arm against minimal resistance. It contracts during ER and relaxes during internal rotation. Cross-fiber flat or pincer palpation may be utilized at the lateral edge of the scapula to identify TrPs (Figure 23-3B).

Figure 23-3. Cross-fiber flat palpation to identify TrPs in the teres minor muscle. A, Patient in prone with arm in 90° of abduction. B, Patient lies on the unaffected side with the affected side supported by a pillow in approximately 30° of abduction.

In an another option for examination, the patient lies on the unaffected side with the uppermost (involved) arm resting on a pillow placed against the chest. The clinician faces the patient and utilizes cross-fiber flat palpation along the lateral edge of the scapula, between the infraspinatus above and the teres major muscle below, to locate TrPs in the teres minor muscle (Figure 23-3). Figure 23-4 illustrates these anatomic relationships with the surrounding muscles. The long head of the triceps brachii muscle passes between the teres minor and teres major muscles, and these muscles form three sides of the quadrangular space (Figure 23-4).

Figure 23-4. Anatomic relations of the teres minor muscle (dark red) to other dorsal scapular muscles (light red). The lateral border of the scapula is usually palpable as an orienting landmark and can be located in the space between the teres minor and the teres major muscles while using pincer palpation. The long head of the triceps muscle also passes through that space and, with the teres minor and teres major muscles and the humerus, helps define the quadrangular (quadrilateral) space.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the teres minor muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.¹⁸ Trigger points may also be activated or aggravated when the muscle is placed in a

shortened and/or lengthened position for an extended period of time.

The teres minor muscle is not usually involved in isolation. Its TrPs are activated by the same overload stresses—reaching up or reaching out and behind the shoulder—that activate TrPs in the infraspinatus muscle (see Chapter 22). Patients may activate acute teres minor TrPs in the following ways: as a result of a motor vehicle accident (particularly when holding on to something such as the steering wheel), by loss of balance while lifting a heavy object overhead, while working in cramped quarters with the arm reaching overhead, and while playing volleyball or other overhead sports.¹³

Teres minor TrPs are perpetuated by continued overloading of the muscle when reaching up and back and by systemic perpetuating factors, as discussed in Chapters 1 to 4.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs in other muscles¹⁹ therefore muscles in the referred pain areas for each muscle should also be considered. The infraspinatus muscle is the primary synergist of the teres minor muscle and clinically, almost always becomes involved when there are TrPs in the teres minor muscle.

Other muscles that should be considered for TrP examination include the supraspinatus muscle, posterior fibers of the deltoid muscle, the teres major muscle, the latissimus dorsi muscle, the scalene muscles, and the levator scapula muscles. In addition, the subscapularis and pectoralis major muscles that are antagonistic to the teres minor muscle in ER of the humerus should be examined as part of the functional unit.

4.3. Associated Pathology

Patients usually do not describe a small arc of severely painful motion with teres minor TrPs; rather, the entire movement or just end of the range of movement is painful. Because the teres minor muscle is one of the rotator cuff muscles, rotator cuff tears should be ruled out. The teres minor muscle is very rarely involved in rotator cuff tears, unless the infraspinatus muscle is also involved.²⁰ To test the integrity of the teres minor muscle, the external rotation lag test, the drop sign, and Patte test can be utilized. A positive external rotation lag test greater than 40° has been shown to have 100% sensitivity in detecting teres minor tears.²¹ In a retrospective study of 279 subjects, investigators found hypertrophic changes in the teres minor muscle in cases where rotator cuff tears included the infraspinatus muscle. The integrity of the teres minor muscle is a prognostic factor for positive outcomes with total shoulder arthroplasty.²²

The teres minor muscle itself does not seem to contribute to axillary nerve entrapment; however, two anatomic variations have been identified in the posterior fascia of the shoulder. One half of the shoulders studied demonstrated a stout fascial sling that the authors believe could be a site for compression and possible tethering of the posterior branch of the axillary nerve to the teres minor muscle. Further understanding of this anatomic abnormality may be helpful when evaluating patients with primary teres minor atrophy and associated reports of pain.²

Quadrilateral space syndrome is characterized by intermittent and poorly localized shoulder pain, paresthesias in the upper extremity in a nondermatomal pattern, point tenderness over the quadrilateral space,²³ and selective atrophy of the teres minor and deltoid muscles.²⁴ This syndrome results from the compression of the axillary nerve by fibrous bands of tissue as the nerve passes through the quadrilateral space. This etiology was demonstrated in three patients by MRI.²⁴ More recently, authors have proposed that quadrilateral space syndrome and isolated teres minor atrophy are distinct clinical entities. The former is typically seen in younger patients and the latter in older adults.^{23,25,26}

As the four case reports of Escobar and Ballesteros¹³ demonstrate, dysesthesia in the fourth and fifth fingers that is caused by active teres minor TrPs can easily be mistaken for an ulnar neuropathy or C8 radiculopathy. The neuropathy and radiculopathy can be ruled out by appropriate electrodiagnostic evaluation.

5. CORRECTIVE ACTIONS

The patient should avoid habitual, sustained, or repetitive motions that overload the teres minor and infraspinatus muscles, such as repetitive overhead lifting with the upper extremity in abduction and ER, and reaching backward into the back seat of the car.

When prescribing or performing neuromuscular reeducation or therapeutic exercises for the teres minor muscle, it is effective to remember that teres minor muscle activation is greater with side-lying ER with the arm at the side and in standing with the shoulder in the plane of the scapula.⁷ The teres minor muscle demonstrates minimal to moderate activity in standing with the arm at the side.^{6,7}

Corrective actions for the teres minor muscle are essentially the same as those described in detail for the infraspinatus muscle (see Chapter 22, Section 5). They include avoidance of excessive or repetitive load on the muscle, correct position of the arm to avoid full shortening during sleep (see Figure 22-4A to C), home application of heat or cold packs, TrP pressure release, and self-stretch exercises.

The patient may inactivate teres minor TrP with the application of TrP compression by lying on a tennis ball placed directly on a tender spot in the muscle or by standing with their back against the wall utilizing the aforementioned technique. In either position, body weight is used to maintain increasing pressure for 1 or 2 minutes, as described in the interventions section. This self-release technique may be repeated several times daily until TrP tenderness disappears. A cold pack may be of therapeutic benefit immediately following pressure release, especially in the case of acute shoulder pain. There are a variety of TrP self-release tools on the market.

Latissimus Dorsi Muscle

“Mid-back Manipulator”

Sophia Maines

1. INTRODUCTION

The latissimus dorsi muscle is an expansive muscle that links the upper and the lower halves of the body through its attachments to the thoracic and lumbar spine via the thoracolumbar fascia and to the proximal humerus. The muscle originates from the spinous processes of T6-L2, the posterior layer of the thoracolumbar fascia, and the posterior aspect of iliac crest lateral to the erector spinae muscles. It inserts onto the humerus at the floor of the intertubercular sulcus. The muscle is innervated by the thoracodorsal nerve from the posterior cord of the brachial plexus. With direct, as well as fascial, connections to the spine, ribs, pelvis, scapula, and humerus, the latissimus dorsi muscle has a myriad of functions for both movement and stability. The muscle functions to extend, adduct, and internally rotate the humerus, and it can influence depression of the shoulder. Its development is key for athletes such as swimmers and baseball players who utilize it for propulsion through the water or throwing. It is one of the most commonly used muscle flaps for a variety of surgical procedures including breast reconstruction. Pain arising due to latissimus dorsi trigger points (TrPs) may be referred to the anterior shoulder, the inferior angle of the scapula, the axillary region, or down the medial aspect of the arm to the fourth and fifth digits. Activities that require straining to reach overhead or out in front of the body, such as hanging, climbing, swimming, or repetitive throwing, may activate and/or perpetuate TrPs in the latissimus dorsi muscle. Differential diagnosis should include cervical radicular pain or radiculopathy, suprascapular nerve entrapment, and bicipital tendinopathy. Altering sleeping posture to prevent prolonged shoulder extension while in a supine position or adduction with internal rotation while lying on the side is essential for managing the patient's pain. Self-stretching and TrP self-pressure release can be very effective in managing symptoms caused by TrPs in the latissimus dorsi muscle.

2. ANATOMIC CONSIDERATIONS

The latissimus dorsi muscle originates from the spinous processes of T6-L2,^{1,2} the posterior layer of the thoracolumbar fascia, and the posterior aspect of iliac crest lateral to the erector spinae muscles¹ (Figure 24-1). The muscle fibers fan from their origins at the trunk toward each shoulder. The upper fibers are nearly horizontal, the middle fibers have a more oblique path, and the lower fibers course almost vertically.¹ The upper fibers pass over, and sometimes attach to, the inferior angle of the scapula.¹ In a study of 100 cadavers, Pouliart and Gagey³ found muscular attachments to the scapula 43% of the time. On others, they observed a small fibrous attachment or an intervening bursa with no connecting tissue. The lower fibers of the latissimus dorsi muscle, which run nearly vertically, have anterior attachments to the lower three or four ribs.^{1,2} In the scapular region, the muscle curves around the inferior border of the teres major muscle, forming the posterior axillary fold.¹ The muscle fibers in this region twist around one another with the lowest originating fibers inserting at the highest point on the humerus and those originating highest at the midline of the body inserting at the lowest point on the humerus.¹ The muscle then inserts onto the humerus at the floor of the intertubercular sulcus, posterior to pectoralis major muscle and anterior to teres major muscle. A bursa separates the latissimus dorsi and teres major tendons near their insertions.¹

Figure 24-1. Attachments of the latissimus dorsi muscle (red), and its relation to the teres major muscle, which arises from the edge of the scapula. The superior (horizontal) fibers of the latissimus dorsi muscle swing around the teres major muscle, and the tendons attach near each other (the teres major muscle to the medial lip of the intertubercular groove of the humerus, and the latissimus dorsi muscle to the floor of the groove). Both muscles are elongated by flexion and external rotation of the humerus.

Rarely, a variant axillary arch muscle has been identified as a slip of muscle extending from the latissimus dorsi muscle's upper border to the humerus, where it inserts deep to the pectoralis major tendon.⁴

2.1. Innervation and Vascularization

The latissimus dorsi muscle is supplied by the thoracodorsal nerve from the posterior cord of the brachial plexus. It arises from the ventral rami of the cervical nerves C6, C7, and C8. The thoracodorsal nerve branches from the posterior cord between the upper and lower subscapular nerves. It accompanies the subscapular artery along the posterior axillary wall, where it supplies the latissimus dorsi muscle.¹

The muscle receives vascular supply primarily from the thoracodorsal artery; the terminal branch of the subscapular artery; from branches of the ninth, tenth, and eleventh posterior intercostal arteries; and the first through third lumbar arteries, which supply the inferior and medial muscle fibers. The thoracodorsal artery enters the muscle near the lateral border and bifurcates into two branches, one that travels parallel to the upper border of the muscle and the other travels medially at a 45° angle. In a rare variation, the thoracodorsal artery can trifurcate with a third branch that may supply the muscle proximally or distally.¹

2.2. Function

With direct, as well as fascial, connections to the spine, ribs, pelvis, scapula, and humerus, the latissimus dorsi muscle has a myriad of functions for both movement and stability. Its primary functions are in the movement and positioning of the upper limb and trunk; it also plays a role in lumbar extension, trunk and pelvic stability, and respiration.

The latissimus dorsi muscle functions to extend, adduct, and internally rotate the humerus and¹ it can also influence shoulder depression.^{5,6} Following a dissection and analysis of the muscle's fascicles, Bogduk and Johnson et al² concluded that the latissimus dorsi muscle's primary actions are movement of the upper extremity and lifting the trunk, such as in a wheelchair transfer.

Using electromyographic (EMG) analysis of the shoulder girdle muscles during various internal rotation exercises, Alizadehkhayat and colleagues⁷ found the greatest activity of the latissimus dorsi muscle with an internal rotation of shoulder elevation at 155° in the scapular plane.

The latissimus dorsi muscle often contributes to power and acceleration movements of the upper limb during various sporting activities such as swimming, throwing, and golfing.⁸ When swimming the butterfly stroke, the latissimus dorsi muscle assists with propulsion through the water.⁹ During the golf swing, it is highly active during the acceleration phase, from a horizontal club position to ball impact.^{10,11} The latissimus dorsi muscle is considered a power muscle, along with the subscapularis, pectoralis major, and serratus anterior muscles for the trail arm to accelerate during the golf downswing.¹²

During the overhead baseball pitch, the latissimus dorsi muscle is most active during the acceleration phase, from maximum shoulder external rotation to ball release,¹²⁻¹⁵ when it works with the subscapularis and pectoralis major muscles for rapid internal rotation of the shoulder.¹² In a study using intramuscular EMG analysis of the throwing shoulder, Jobe et al¹⁶ found that the activity of pectoralis major and latissimus dorsi muscles occurred at the end of the cocking phase and continued through the acceleration phase. They concluded that these two muscles provided the “power and driving force” of forward shoulder movement. Comparing the muscle activity of professional against amateur pitchers, Gowan et al¹⁷ found that professional pitchers demonstrated a stronger activity of latissimus dorsi and subscapularis muscles than amateurs.

Surgical transfer of the latissimus dorsi muscle most often leads to deficits of endurance in shoulder extension and adduction, observed on an earlier onset of fatigue with activities such as swimming or ladder climbing.¹⁸ In a study involving 26 men and women, Fraulin et al¹⁹ found deficits in power as well as endurance of shoulder adduction and extension post transfer.

Studies have sought to functionally differentiate the parts of the muscle.²⁰ In one such study involving a surface EMG analysis of 17 subjects, Park and Yoo⁵ separated the muscle into medial and lateral compartments. They examined the medial compartment with a surface electrode placed over the muscle belly lateral to T9. Activity in the lateral compartment was observed with an electrode placement 4 cm below the inferior angle of the scapular midway between the spine and the lateral edge of the torso. They found more activity in the medial compartment with shoulder adduction, extension, and internal rotation, whereas more activity was present in the lateral compartment with shoulder depression. Paton and Brown²⁰ found functional differentiation within the latissimus dorsi muscle when they used surface EMG to record isometric muscle contractions. They concluded that adduction from an abducted position preferentially involved the muscle’s most caudal fibers, whereas isometric adduction in the anatomic position involved muscle activity across the entire muscle.

The latissimus dorsi muscle also functions as an accessory muscle for respiration, with both deep inspiration and forced expiration as with coughing.¹

Whereas the latissimus dorsi muscle is generally recognized for its role in the movement of the upper limb, its fascial connections have been investigated for their contribution to lumbar movement and trunk and pelvic stability. The latissimus dorsi aponeurosis is continuous with the superficial lamina of the posterior layer of the thoracolumbar fascia.

This fascial layer also has fibrous connections with the trapezius, gluteus maximus, and external oblique muscles.²¹ In a study involving embalmed cadavers, Vleeming et al²² found that traction on the latissimus dorsi muscle displaced the superficial lamina both ipsilaterally and, in some areas, contralaterally. Similarly, a study involving unembalmed cadavers found that tensioning the latissimus dorsi muscle displaced the posterior layer of the lumbar fascia.²³ When studied in vivo, researchers observed that tensioning of the latissimus dorsi muscle produced myofascial force transmission, likely through the thoracolumbar fascia, which moved the contralateral hip into external rotation.²⁴ Mooney et al²⁵ used surface EMG to confirm a reciprocal relationship between the latissimus dorsi and the contralateral gluteus maximus muscles during a torso rotation exercise and gait in healthy participants.

In a study of force closure of the sacroiliac joint (SIJ) involving six subjects, muscle activation was found to effect SIJ stiffness, although activation of the latissimus dorsi muscle was found to have only a small effect, less than that with activation of the erector spinae, biceps femoris, and gluteus maximus muscles. One subject was able to nearly isolate the latissimus dorsi muscle with no change in joint stiffness. The authors reported that SIJ stiffness found in other subjects with latissimus dorsi muscle activation could be due to activity of other muscles.²⁶

The latissimus dorsi muscle's contribution to lumbar extension has also been studied. Mathematical models used to study how tension from the latissimus dorsi muscle on the lumbodorsal fascia could affect the extension moment on the spine during a dynamic squat lift found negligible contributions on extension during the lifts studied.²⁷ De Ridder et al²⁸ used functional MRI to study muscle activation during prone trunk and leg extension exercises and found the latissimus dorsi muscle was the least activated muscle compared with the paraspinal and multifidi muscles.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 24-1 grossly represents the functional unit of the latissimus dorsi muscle.²⁹

Box 24-1 Functional unit of the Latissimus Dorsi muscle¹⁸

Action	Synergists	Antagonists
Shoulder internal	Subscapularis	Infraspinatus

rotation	Pectoralis major Teres major Anterior deltoid	Teres minor Posterior deltoid
Shoulder extension	Teres major Triceps brachii Posterior deltoid	Anterior deltoid Long head biceps brachii Coracobrachialis
Shoulder adduction	Pectoralis major Teres major Coracobrachialis	Middle deltoid Supraspinatus
Shoulder girdle depression	Teres major Pectoralis major External abdominal oblique	Scalene muscles Upper trapezius

When the arm is abducted, the latissimus dorsi muscle works with the triceps brachii muscle to stabilize the glenohumeral joint. When the arm is by the side of the body, the latissimus dorsi muscle and the long head of the triceps brachii muscle act as antagonists of glenohumeral joint stabilization. The latissimus dorsi muscle also works with the external abdominal oblique muscle to stabilize the lower ribs.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The latissimus dorsi muscle is a frequently overlooked cause of mid-thoracic back pain of myofascial origin. Trigger points are commonly found in the posterior axillary fold (Figure 24-2A). Pain may refer to the inferior angle of the scapula and ipsilateral mid-thoracic region. It also may extend to the posterior aspect of the shoulder, down the medial aspect of the arm, forearm, and hand to the fourth and the fifth fingers (Figure 24-2B).

Figure 24-2. Referred pain patterns (essential portion is solid red, spillover portion is stippled red) referred from TrPs in the right latissimus dorsi muscle. A, Back view of the pain pattern from TrPs in their most common location within the axillary portion of the muscle. B, Front view of the same. C, Right latissimus dorsi muscle and attachments. D, Pain pattern of TrPs in the inferior portion of the muscle which may also refer pain down the arm.

Trigger points may also be present at the lateral aspect of the muscle in the region of the lower ribs (Figure 24-2C, D). Trigger points in this area commonly refer pain to the front of the shoulder and to the side of the torso above the iliac crest. A TrP in the thoracolumbar region may refer pain locally to the inferior aspect of the posterior axillary fold.³⁰

In a study using 7.5% saline injections to determine referred pain patterns, injection to the vertically oriented fibers in the axillary region next to teres major muscle most commonly referred pain to the dorsum at the scapular region. Injection to the superficial, horizontal fibers most commonly referred pain to the upper limb.³¹

Pain patterns have not been identified for the latissimus dorsi muscle's anterior fibers that attach to the ribs. Some cases of low back pain have historically been attributed to latissimus dorsi dysfunction in the lumbosacral area, but this pain may have been caused by enthesopathy.³²

3.2. Symptoms

Patients with TrPs in the latissimus dorsi muscle usually do not report pain until the TrPs are active and cause pain at rest. Furthermore, patients are often unable to identify a particular activity that aggravates their pain. They may give a long history of negative diagnostic procedures, such as bronchoscopy or computerized tomography, as well as a history of unsuccessful therapy aimed at the area of referred pain in the back rather than at its source.

The patient with latissimus dorsi TrPs may report a constant aching pain referring to the inferior scapular angle and surrounding mid-thoracic region. When asked to draw the pain, a patient is apt to mark a circle centered on the inferior scapular angle. Alternatively, pain from TrPs in the latissimus dorsi muscle can also mimic cervical radicular pain with symptoms down the posterior and/or medial aspects of the arm into the fingers. Numbness and tingling along this area are frequently reported.

Pain from TrPs in the latissimus dorsi muscle may be recreated by shoulder girdle depression movements that load the muscle or weighted overhead stretching in front of the body, such as to retrieve an object from a high shelf.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing

representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For a proper examination of the latissimus dorsi muscle, the clinician should observe shoulder girdle and trunk posture and scapular position, examining active and passive ranges of motion of the shoulder girdle and taking note of muscle activation patterns and the scapulohumeral rhythm.

To identify TrPs in the latissimus dorsi muscle that may be limiting the range of motion and thus influencing dysfunction, the clinician should identify the limited range of motion by performing specific range of motion tests for all parts of the latissimus dorsi muscle. Because a patient with latissimus dorsi TrPs often presents with a shoulder range of motion limitations, a thorough examination of all contributing factors to the lost range of motion should be completed.

There are several variations of testing procedures for latissimus dorsi muscle length. In the Vladimir Janda approach, the patient lies supine with knees bent and feet on the table. The clinician moves one of the patient's arms through shoulder elevation. According to this assessment, with sufficient latissimus dorsi muscle length, the lumbar spine should remain flat on the table and not extended when the arm is horizontal and resting on the table. Extension of the spine or lack of full shoulder elevation motion may indicate muscle shortness.³³

Accessory joint motions of the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic joints should be tested. The thoracic spine, rib cage, and lumbar intervertebral accessory joint motion should also be assessed manually. Often, joint hypomobility in the sternoclavicular joint, thoracic spine, and rib cage can cause impairment in shoulder elevation, contributing to alterations in the normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns contributing to the overload of the latissimus dorsi and other shoulder girdle muscles.

3.4. Trigger Point Examination

Clinical examination may be performed in supine, prone, or a side-lying position (Figure 24-3A to C). The side-lying position is preferred as the entirety of the muscle is accessible, and the clinician is able to see the patient's face during the examination. When examining the left latissimus dorsi muscle, the patient should be positioned on the right side with left arm elevated and placed on a pillow. The clinician can cue the patient to adjust trunk flexion and extension as needed. Trigger points in the dorsal and caudal fibers can be palpated with a cross-fiber flat palpation (Figure 24-3A). The clinician should be cognizant of fiber direction to ensure accuracy with palpation. The most lateral fibers, which attach to the iliac crest, are the most vertical and run about 15° to the sagittal plane.² Fiber direction, which is always oblique, becomes more horizontal superiorly with fibers from the thoracic region running about 50° to 60° to the sagittal plane.² Cross-fiber pincer palpation may also be used in the axillary region or at the lateral trunk to identify TrPs (Figure 24-3B, C).

Figure 24-3. Palpation of the latissimus dorsi muscle. A, Side-lying cross-fiber flat palpation. B, Supine cross-fiber pincer palpation in the axillary region. C, Prone cross-fiber pincer palpation at the lateral trunk.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the latissimus dorsi muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position, such as side sleeping or sitting with increased internal rotation of the shoulders. Compression from a restrictive undergarment or bra can also activate and perpetuate TrPs and may be implicated if there is visible indentation from the band on the skin.

Finding the source of TrPs in the latissimus dorsi muscle requires a careful analysis of activities that require repetitive shoulder girdle depression, shoulder extension or adduction, or trunk movement. Activities that utilize the latissimus dorsi muscle and may activate TrPs include walking with axillary crutches, wheelchair use or wheelchair transfers, throwing, and climbing or hanging from the upper limbs.² Activities that require straining to reach overhead or out in front of the body may also activate and/or perpetuate TrPs in the latissimus dorsi muscle.

4.2. Associated Trigger Points

Muscles in the referred pain areas of the latissimus dorsi muscle should be considered because associated TrPs can develop within them.³⁵ These include the biceps brachii, deltoid, coracobrachialis, flexor carpi ulnaris, triceps brachii, infraspinatus, teres major, trapezius, rhomboids, and abdominal oblique muscles.

The teres major muscle frequently develops TrPs with the latissimus dorsi muscle due

to its anatomic proximity. Similarly, the long head of the triceps brachii muscle is also prone to associated TrPs, particularly in chronic cases.

Because the latissimus dorsi muscle is one of 13 muscles that refer pain to the medial border of the scapula, the other referring muscles should also be considered when pain here is reported. These include the scalenes, cervical and thoracic multifidi, levator scapula, rhomboid major and minor, serratus anterior, serratus posterior superior, iliocostalis thoracis, infraspinatus, and the middle and lower trapezius muscles.

4.3. Associated Pathology

The latissimus dorsi muscle (along with the pectoralis major, teres major, and subscapularis muscles) is implicated in myofascial presentation of thoracic outlet syndrome. Referred pain from any one of these four muscles can mimic thoracic outlet syndrome. Trigger points in at least three of these muscles are strongly suggestive of the syndrome and often misdiagnosed as such, though these muscles do not cause compression of structures in the thoracic outlet. The thoracic outlet syndrome is further discussed in Chapter 33.

Other conditions that should be considered include cervical radicular pain or radiculopathy, bicipital tendinopathy, and entrapment of the suprascapular nerve at the spine of the scapula.

Both latissimus dorsi and quadratus lumborum TrPs have been associated with innominate dysfunction. However, the muscles have distinctly different pain referral patterns. Quadratus lumborum TrPs are associated with sacroiliac dysfunction, whereas isolated latissimus dorsi TrPs are associated with innominate upslips. Therefore, a positive SIJ testing may implicate quadratus lumborum muscle involvement, but not the latissimus dorsi muscle.²⁹

5. CORRECTIVE ACTIONS

A patient with latissimus dorsi TrPs should avoid habitual, sustained, or repetitive motions that overload the latissimus dorsi muscle. These motions may include retrieving heavy objects from a shelf that requires straining or overreaching or activities that require excessive pulling such as gymnastics, tennis, swimming, rowing, chopping wood, or throwing.

Sleeping positions can be particularly troublesome for assuming prolonged aggravating postures. The individual with latissimus dorsi TrPs may be most comfortable sleeping on the back or on the pain-free side. When lying on the uninvolved side, sleep may be improved by supporting the uppermost elbow and forearm of the painful limb on a pillow (Figure 22-4A) in a neutral position to avoid prolonged shortening of the affected latissimus dorsi muscle that can cause referred pain. This pillow positioning technique can also help keep the arm in a neutral position while lying on the back (Figure 22-4C). Another option is to place the pillow under the arm perpendicular to the body to keep the arm out of adduction and internal rotation and in a resting length-tension position for the latissimus dorsi muscle. Patients should be cautioned regarding lying in bed with their

arm(s) above their head in an abducted and an externally rotated position, as this position keeps the latissimus dorsi muscle in a prolonged lengthened position and may cause increased tensile stress in the muscle.

A patient can also learn self-treatment for latissimus dorsi TrPs using a round TrP self-release tool (Figure 24-4A, B). The patient lies on the affected side with the shoulder abducted to stretch the latissimus dorsi muscle. The body position is adjusted over the tennis ball at the TrP site. A gentle pressure is applied while the patient performs gentle isometric contractions followed by muscle relaxation. The patient can perform manual self-pressure release of TrPs by grasping the muscle belly where it is most tender (Figure 24-4C). The patient should be instructed to exhale during the relaxation phase to encourage muscle relaxation.

Figure 24-4. TrP self-release. A, Self-pressure release of TrPs with tool. B, Lying on tennis ball. C, Manual self-pressure release of TrPs.

The patient can be instructed in a self-stretch for the muscle as well. The patient begins in a quadruped position and then move backward into a “child’s pose,” achieved by bringing the buttocks to rest on the feet and chest atop the knees with arms forward on the floor. To stretch the left side of the muscle, the patient can walk the hands along the floor to the right. The patient can modify the stretch by turning the palm up on the side that is being stretched (Figure 24-5).

Figure 24-5. Latissimus dorsi muscle self-stretch. The patient can begin in child's pose, then walk the hands away from the side being stretched. The exercise can be modified by internally or externally rotating the arm.

Teres Major Muscle

“Forgotten Shoulder Aggravator”

Sophia Maines

1. INTRODUCTION

The teres major muscle is a thick, round muscle that is significantly shorter than its neighbor, the latissimus dorsi muscle. The teres major muscle originates from the inferior angle of the scapula and travels laterally to insert on the medial lip of the bicipital groove. The teres major attachment on the lowest part of the scapula becomes the superior attachment on the humerus, twisting like its counterpart, the latissimus dorsi muscle. This unique arrangement of fiber orientation allows it to generate exceptional tensile forces. The teres major muscle is entwined with the larger latissimus dorsi muscle in the posterior axillary fold. It is innervated by the lower subscapular nerves, C5, C6, and C7, and it assists the latissimus dorsi muscle with shoulder internal rotation as well as shoulder adduction and extension. The teres major muscle refers pain to the region of the posterior deltoid muscle, posterior glenohumeral joint, over the long head of the triceps brachii muscle, and occasionally into the posterior aspect of the forearm. Patients often report minimal pain at rest but sharp pain in the posterior shoulder with overhead movements, especially with retrieving items from a high shelf. Trigger points (TrPs) are easily activated and perpetuated by activities that require excessive amounts of pulling such as rowing, playing tennis, or throwing. The teres major muscle is a common site for TrPs in patients with unilateral, nontraumatic shoulder pain, and it should be examined when patients report pain, weakness, tenderness, or paresthesias in the upper quarter. Altering the sleeping posture to prevent prolonged shoulder extension while supine, or adduction with internal rotation while lying on the side, is essential for managing pain. Self-stretching and TrP self-pressure release can be very effective in managing symptoms caused by TrPs in the teres major muscle.

2. ANATOMIC CONSIDERATIONS

The teres major muscle originates from the middle third of the lateral posterior aspect of the scapula;¹ from the inferior angle of the scapula, and from a fibrous septa between the teres minor muscle and the infraspinatus muscle (Figure 25-1). Its fibers spiral laterally toward the humerus, passing anteriorly to the long head of triceps brachii muscle, where they insert onto the medial aspect of the intertubercular sulcus of the humerus.² Roughly 4 cm in width, the teres major tendon inserts posterior to the latissimus dorsi tendon.³ In a study of cadavers, Pearle et al³ found variable merging of the teres major and latissimus dorsi tendons near their insertion site. Due to its spiraling structure, similar to that of the latissimus dorsi muscle, the lowest portion of the origin of the muscle on the scapula is attached to the highest point of its insertion on the humerus. Therefore, the fibers of the teres major muscle that originally faced posterior at its origin, face anterior at its insertion.¹

Figure 25-1. Attachments of the teres major muscle. See Figure 24-2 for its anatomic relation to the latissimus dorsi muscle, and Figure 26-3 for its relation to other shoulder girdle muscles.

The teres major muscle marks a border for several clinically important regions including the upper and lower triangular spaces and the quadrangular space. The upper triangular space, which houses the circumflex scapular vessels, is bordered by the teres major muscle inferiorly. The other borders are the subscapularis, teres minor, and the long head of the triceps brachii muscles. The lower triangular space, which contains the radial nerve and profunda brachii vessels, is bordered by the subscapularis muscle, the long head of the triceps muscle, and the humerus. The teres major muscle forms its posterior border.²

The quadrangular space contains the axillary nerve and posterior circumflex humeral artery and veins. The teres major muscle forms its inferior boundary. It is bordered by the long head of the triceps brachii muscle medially and the humerus laterally. At its anterior aspect, the superior borders are the subscapularis muscle, the glenohumeral joint capsule, and the teres minor muscle. Posteriorly, its superior border is the teres minor muscle.²

2.1. Innervation and Vascularization

The teres major muscle is innervated by the lower subscapular nerves, C5, C6, and C7.² A variant nerve supply from the thoracodorsal nerve has also been identified.⁴

The teres major muscle receives its vascular supply from either the thoracodorsal artery or the circumflex scapular artery, both of which are branches of the subscapular artery.⁴

2.2. Function

The teres major muscle is a thick fusiform muscle able to produce great tensile forces due to its shape and structure. The teres major muscle and the latissimus dorsi muscle have very similar actions at the glenohumeral joint.¹ The teres major muscle assists with shoulder extension, adduction, and internal rotation.^{2,5} Perhaps more interesting is its role in static posture and arm swing during gait.² The muscle is active during the backward arm swing.⁶ Studies also have found that the muscle is active during typing, handwriting, and turning a car steering wheel.^{5,7,8} In a small study, the teres major muscle was found to be active during shoulder depression, adduction behind the line of the body, and extension.⁵

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 25-1 grossly represents the functional unit of the teres major muscle.⁹

Box 25-1 Functional Unit of the Teres Major Muscle

Action	Synergists	Antagonist
Shoulder internal rotation	Latissimus dorsi Pectoralis major Subscapularis	Infraspinatus Teres minor
Shoulder extension	Latissimus dorsi Posterior deltoid Triceps brachii long head	Anterior deltoid Pectoralis major Biceps brachii long head Coracobrachialis
Shoulder adduction	Pectoralis major Latissimus dorsi Subscapularis Coracobrachialis	Deltoid Supraspinatus

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The prevalence of teres major TrPs in patients with shoulder pain may be higher than thought earlier. In an observational study of 72 patients with nontraumatic unilateral shoulder pain, Bron et al¹⁰ observed latent TrPs in the teres major muscle in 49% of subjects. These were the most frequently observed latent TrPs, followed by anterior deltoid TrPs found in 38% of the patients.¹⁰

Trigger points in the teres major muscle are most commonly found in three areas. Medially, TrPs may be found in the region of the inferior angle of the scapula. They may also be found in the middle of the muscle in the posterior axillary fold, where the teres major muscle is overlapped by the latissimus dorsi muscle. Last, TrPs are often located laterally in the region of the musculotendinous junction.

Trigger points in this muscle commonly refer pain to the posterior deltoid region and to the region of the long head of the triceps brachii muscle (Figure 25-2A to C). Trigger points may refer pain into the posterior aspect of the glenohumeral joint and occasionally, to the posterior aspect of the forearm.

Figure 25-2. Referred pain pattern of teres major muscle. A, Posterior view. B, Anterior view of referred pain patterns (essential portion is solid red, spillover portion is stippled red) referred from C, Right teres major muscle.

3.2. Symptoms

Patients with TrPs in the teres major muscle may complain of mild pain at rest; however the primary complaint often is pain with motion. Patients often report sharp pain in the posterior aspect of the shoulder, especially when reaching up to retrieve an object from a shelf or cabinet. Pain in the teres major muscle is often elicited by a stretching movement such as passive shoulder flexion, abduction, or external rotation.¹¹ Similarly, pain may occur with loading during resisted shoulder extension or internal rotation of the humerus.¹¹

Teres major muscle involvement does not significantly restrict shoulder movement as observed with adhesive capsulitis, but patients may experience significant pain, which limits full overhead range of motion.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change.

Proper assessment of the teres major muscle should include examination of shoulder range of motion and strength. Patients with TrPs in the teres major muscle may exhibit weakness or pain with resisted testing. Increased upward scapular rotation can be observed with shoulder flexion secondary to restrictions in the teres major muscle length. Limited shoulder abduction with an inability to bring the involved arm in contact with the ear can

suggest TrPs in the teres major muscle. Frequently, involvement of this muscle causes pain at the end of the range of motion. Restrictions of 3 to 5 cm (1-2 in) and/or pain with the Apley's scratch test (abduction, flexion, and external rotation) may also suggest teres major muscle involvement (Figure 21-3).

3.4. Trigger Point Examination

Once the teres major muscle is identified properly, the reliability of identifying TrPs should be comparable with that of the latissimus dorsi muscle. In a study of reliability of TrP examination, Gerwin et al¹² included the latissimus dorsi muscle among four muscles examined. They reported a high degree of agreement for the detection of a taut band, the presence of spot tenderness, referred pain, and reproduction of the symptomatic pain.

Clinical examination may be performed in a supine (Figure 25-3A), prone (Figure 25-3B), seated, or side-lying position. For all these positions, a cross-fiber flat palpation may be utilized to detect taut bands and TrPs. Cross-fiber pincer palpation may also be utilized to identify TrPs in the mid-muscle belly; however, the clinician should be able to differentiate between the latissimus dorsi and teres major muscles.

Figure 25-3. Examination of TrPs in the teres major muscle. In the axilla, the examiner's digits should fully encompass the latissimus dorsi muscle to reach the teres major muscle. The groove between the teres major and the latissimus dorsi muscles is confirmed when the examiner's finger tips can identify the lateral border of the scapula between the two muscles. A, Patient supine; B, Patient prone.

To examine the muscle in the supine position, the shoulder should be positioned in 90° of shoulder abduction and external rotation (Figure 25-3B). Landmarks to locate the teres major muscle include the axillary border of the scapula cranially, the latissimus dorsi muscle, and the inferior border of the scapula caudally. To locate the axillary border of the scapula, the clinician can use deep pincer palpation of the axillary fold approximately 1 in below the humerus. This location is cranial to the teres major muscle's attachment site on the scapula. Just caudal to this site lies a palpable groove between the scapular border and the teres major muscle. Sliding the pincer grasp slightly caudally allows palpation of the axillary portion of teres major muscle. Below this location, at the level of the inferior angle

of the scapula, lies the latissimus dorsi muscle. The latissimus dorsi muscle forms the free border of the posterior axillary fold as it wraps around the teres major muscle. The clinician may instruct the patient to perform shoulder internal rotation to confirm the location of the muscle.

The muscle is easily palpated in the prone position with the arm abducted 70-90° and the forearm off the table. Resisted shoulder internal rotation helps distinguish the muscle from the teres minor and latissimus dorsi muscles.

To access the muscle in a side-lying position, the patient lies on the uninvolved side with the involved arm resting on a pillow. The teres major muscle can be located in the axillary fold by following its fibers from the dorsal surface of the scapula. Cross-fiber flat palpation across the fibers can be used to locate TrPs in the region of the lateral border of the lower third of the scapula.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the teres major muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.¹³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. Inquiry into possible aggravating activities such as sitting or standing with the shoulder in a position of increased internal rotation, prolonged driving with exertional movement of the steering wheel, or repetitive shoulder movement is necessary to modify behaviors that might result in continued pain. Activities that require excessive pulling actions such as playing tennis or golf, rowing, and throwing a ball may also activate TrPs in the teres major muscle. Finding the driving cause of these TrPs requires careful analysis of activities that require repetitive shoulder extension, internal rotation, or adduction.

4.2. Associated Trigger Points

Trigger points may develop in muscles in the referred pain area from other muscles that have TrPs.¹⁴ Muscles that can develop TrPs due to pain referral from teres major TrPs include the posterior deltoid, middle deltoid, the long head of the triceps, and the wrist extensor muscles. Trigger points in the teres major muscle can also develop due to TrPs of other muscles including the deltoid, the subscapularis, and the latissimus dorsi muscles.

Clinically, associated TrPs have also been located in the latissimus dorsi muscle. Involvement of the teres minor and subscapularis muscles may lead to pain and significant functional impairment in a condition that can mimic “frozen shoulder.”

4.3. Associated Pathology

The teres major muscle (along with latissimus dorsi, pectoralis major, and subscapularis

muscles) is one of the four muscles implicated in myofascial pseudothoracic outlet syndrome. Active TrPs in at least three of these muscles is strongly suggestive of thoracic outlet syndrome and often misdiagnosed as such. However, these muscles do not cause compression of the neurovascular structures of the thoracic outlet. Implications of myofascial dysfunction in thoracic outlet syndrome are further discussed in Chapter 33.

Other conditions that can mimic teres major TrPs include subacromial or subdeltoid bursitis, supraspinatus tendinopathy, and C6-C7 radicular pain and/or radiculopathy. The associated pathology also includes triangular interval syndrome and quadrilateral space syndrome.

Sebastian¹⁵ described a case study of triangular interval syndrome. The patient presented with right scapular pain with radiating symptoms into the posterior arm to the radius. Onset of symptoms, described as sharp and shooting pain, followed punching during a kickboxing class. Testing did not meet the standards for the clinical prediction rule established by Wainer et al¹⁶ for cervical radiculopathy. The patient demonstrated a negative Spurling's test, relief of symptoms with cervical distraction, and ipsilateral neck rotation greater than 60°. The patient had a positive radial nerve-biased upper limb tension test. On palpation, the patient exhibited tenderness at the long and lateral heads of the triceps brachii muscle superiorly and at the lateral portion of the teres major muscle along with reduced pain pressure threshold with reproduction of the patient's symptoms. After the patient was treated for soft-tissue dysfunction at the triangular interval and adverse radial nerve tension, resolution of symptoms was reported.¹⁵

Patients with quadrilateral space syndrome, a rare condition of compression of the axillary nerve and posterior circumflex artery, may report symptoms of shoulder pain, tenderness, and paresthesias aggravated by shoulder abduction and rotation.¹⁷⁻¹⁹

5. CORRECTIVE ACTIONS

The patient with teres major TrPs should modify any activity that repeatedly stresses the muscle, such as prolonged driving and lifting weights overhead. To prevent full shortening of this muscle while sleeping on the affected side, a small pillow can be placed between the elbow and the lateral aspect of the trunk to maintain a neutral position of the muscle (Figure 22-4C). A pillow support can also be used for this purpose while sleeping on the uninvolved side (Figure 22-4A).

The patient can self-treat the muscle with TrP self-pressure release utilizing a tennis ball or TrP self-pressure release tool in a technique similar to that used for the latissimus dorsi muscle (Figure 25-4). The patient lies on the affected side with the shoulder flexed to stretch the muscle. Body position can be adjusted over the tennis ball at the TrP site. This treatment could also be performed in a sitting position with pressure applied using the opposite hand with or without a tennis ball. The patient can also perform pressure release by grasping the muscle belly between the thumb and fingers and holding compression for 15 to 30 seconds, repeating as necessary (Figure 25-5).

Figure 25-4. To self-treat the teres major muscle. The patient lies on the involved side with the shoulder flexed and the tennis ball situated in the axillary region, slightly posterior to the latissimus dorsi muscle. A gentle pressure is applied. The patient may perform gentle isometric contractions by pushing the elbow gently into the floor and holding for 6 to 10 seconds followed by relaxation.

Figure 25-5. The patient can perform manual TrP self-pressure release by grasping the teres major muscle between the thumb and fingers holding compression for 15 to 30 seconds, repeating as necessary.

Stretching techniques for this muscle are similar to those for the latissimus dorsi muscle

(Figure 24-5); however, it is important to stabilize the scapula from abducting for maximal efficacy.

Subscapularis Muscle

“Pseudo Frozen Shoulder”

Joseph M. Donnelly and Laura Gold

1. INTRODUCTION

The subscapularis muscle is the largest of the four rotator cuff muscles. It attaches to the periosteum of the costal surface of the scapula beneath the serratus anterior muscle from its vertebral border to the axillary border. Other fibers attach at the intramuscular septa and aponeurosis separating the subscapularis muscle from the lateral scapular musculature. The tendon attaches anteriorly at the lesser tubercle of the humerus and anterior articular capsule. The subscapularis muscle is innervated by the upper and lower subscapular nerves, branches of the posterior cord of the brachial plexus that arise from spinal levels C5 and C6. It is responsible for internal rotation and adduction of the humerus, as well as dynamic stabilization of the glenohumeral joint along with the other rotator cuff muscles. One of the most important functions of the subscapularis muscle is to provide dynamic restraint to the posterior aspect of the glenohumeral joint. Trigger points (TrPs) in the subscapularis muscle will produce severe pain in the posterior shoulder that can refer down the back of the arm and to the dorsal and volar aspect of the wrist. Subscapularis TrPs often play a role in frozen shoulder syndrome (FSS). Trigger points in this muscle are frequently the foundation in a tower of shoulder dysfunction. Symptoms may be aggravated by sleeping on the affected side, reaching the arm out to the side, or performing functional activities that require flexion and adduction. Activation and perpetuation of TrPs in the subscapularis muscle usually result from acute overload, repeated forceful overhead lifting while exerting strong adduction forces, and catching oneself from a fall with an outstretched arm. Differential diagnosis should include assessment for posterior glenohumeral joint capsule tightness; C5, C6, or C7 radicular pain; subacromial pain (impingement) syndrome (SIS); FSS (adhesive capsulitis); rotator cuff pathology; thoracic outlet syndrome; and scapulothoracic or subacromial bursitis. Corrective actions should include postural reeducation (including proper sleep position), elimination of positions that cause recurrent overload on the muscle, self-pressure release of TrPs, and self-stretch

exercises. Clinically, this muscle produces an easily recognizable, distinct pain pattern that may be key in unraveling a number of shoulder conditions, both acute and chronic in nature.

2. ANATOMIC CONSIDERATIONS

The subscapularis muscle is the largest and most anterior of the four rotator cuff muscles. The subscapularis muscle has two heads, and its triangular mass fills the subscapular fossa.¹ The subscapularis muscle is quite thick and has a similar arrangement to that of the infraspinatus muscle in that the muscle fibers converge from a broad medial portion toward a central tendon that covers the anterior aspect of the glenohumeral joint.² Medially, the subscapularis muscle attaches to the periosteum of the costal surface of the scapula beneath the serratus anterior muscle from its vertebral border to the axillary border. Other fibers attach at the intramuscular septa and aponeurosis, separating the subscapularis muscle from the lateral scapular musculature. Multipennate in appearance, the horizontally oriented superior fibers converge with the more vertically oriented inferior fibers to form a tendon that runs laterally and attaches anteriorly at the lesser tubercle of the humerus and anterior articular capsule (Figure 26-1). The thick inferior head of the subscapularis muscle provides a majority of the structure of the subscapular tendon. Cleeman et al³ performed a detailed cadaveric dissection of the tendon insertion of the subscapularis muscle. They describe the subscapularis tendon as consisting of three distinct sections: “a thick superior tubular tendon, a flat middle tendon, and an inferior portion where the muscle fibers insert directly into the humerus.” The cross-sectional area of the subscapularis tendon is the largest of all tendons in the shoulder, and it dynamically reinforces the glenohumeral ligaments and the anterior glenoid labrum.² The large subscapular bursa, which usually communicates with the cavity of the shoulder joint, separates the tendon from the scapular neck and joint capsule medially.¹

Figure 26-1. Attachments of the right subscapularis muscle, as seen from the front with the arm externally rotated. Parts of ribs two through five have been removed for clarity.

2.1. Innervation and Vascularization

The subscapularis muscle is innervated by the upper and lower subscapular nerves, branches of the posterior cord of the brachial plexus that arise from spinal levels C5 and C6.¹ Two upper subscapular nerves typically supply the upper portion of the subscapularis muscle, whereas the lower subscapular nerve, which terminates in the teres major muscle, supplies the lower, more distal, portion of the muscle. The separate innervation of these upper and lower fibers is consistent with the findings of Electromyography (EMG) studies that show these “compartments” as functioning independently.⁴⁻⁶

The vascular supply of subscapularis muscle comes from branches off the suprascapular, axillary, and subscapular arteries.¹ Detailed cadaveric dissection described by Serita et al,⁶

however, revealed variable distribution that also included supply from the circumflex scapular, brachial, thoracodorsal, and lateral thoracic arteries. These authors also noted correspondence between areas of relatively poor vascular supply (ie, possible areas of local ischemia) and common possible locations for TrPs in the rotator cuff muscles.⁶

2.2. Function

The subscapularis, infraspinatus, teres minor, and supraspinatus muscles are inserted, respectively, into the lesser and greater tuberosities of the humerus and form a musculotendinous rotator cuff. These rotator cuff muscles provide dynamic stability to the glenohumeral joint. Motion at the shoulder joint is a complex coordinated activity and the moment arms of the rotator cuff muscles exert inferior and medially directed forces, resisting upward shear of the deltoid muscle during shoulder elevation while keeping the head of the humerus in close contact with the glenoid fossa.⁷ The subscapularis muscle functions alone as a powerful internal rotator of the humerus, but equally important is its role as a dynamic stabilizer of the glenohumeral joint.^{1,8} The subscapularis muscle prevents anterior displacement of the humeral head, especially in lower ranges of abduction.^{9,10} It is also established as acting in concert with the infraspinatus muscle to depress the humeral head in opposition to the upward displacement caused by the deltoid muscle during arm elevation.^{11,12} Heuberger et al¹² published data from an EMG study supporting that the subscapularis muscle has a major role during glenohumeral flexion and abduction. The authors speculate at the possibility of the subscapularis muscle acting as an abductor given the superior portion of the tendon's high insertion point on the lesser tubercle of the humerus (rather than solely stabilizing during the motion). In contrast, it has been previously reported that the subscapularis muscle functions as a humeral adductor.¹³ This dual functionality may be possible given the likely separate roles of the upper and lower muscular compartments. A number of EMG studies reinforce the idea that the subscapularis muscle is composed of two (upper and lower) functional units^{5,14}; however, consensus has not been reached regarding the specific role each functional unit plays except to note that varying degrees of abduction result in differing levels of activation in the upper and lower units.

Reed et al¹⁵ studied the influence of loads on the recruitment patterns of the rotator cuff muscles during abduction. They found that the activation patterns that were established with low loads continued as the load increases and they concluded that the role of the subscapularis and infraspinatus muscles is to counterbalance the upward migration of the humerus caused by the strong torque produced by the middle deltoid. The patterns of activation of the subscapularis and infraspinatus muscles were strongly correlated to the axioscapular muscle activation pattern.¹⁵ In another study looking at shoulder abduction in the plane of the scapula and coronal plane, it was found that all rotator cuff muscles activated before movement of the humerus during all abduction movements.⁷ The subscapularis muscle was recruited later than the other three rotator cuff muscles but still before humerus motion. They conclude that shoulder abduction in the coronal plane and

elevation in the plane of the scapula is a complex coordinated activity initiated and controlled by several muscles.⁷ Wickham et al¹⁶ found the upper and lower subscapularis peak muscle activation to be 18% and 25% maximum volitional contraction (MVC) between 80° and 120° of abduction, respectively.

EMG analysis of the rotator cuff muscles was performed during forward flexion with no load, 20%, and 60% of the subject's maximum load. These studies found that the supraspinatus and infraspinatus muscles were activated at significantly higher levels than the subscapularis muscle at all load levels. The authors conclude that the posterior rotator cuff muscles are recruited at higher levels to prevent translation of the humeral head during flexion similarly to the inferior cuff muscles during abduction.^{7,17}

EMG analysis of subscapularis muscle activity during functional movements is well documented, especially in sporting activities. Jobe et al¹⁸ and Gowan et al¹⁹ investigated muscle activation patterns and activity during throwing movements. They identified maximum activity of the supraspinatus, infraspinatus, and deltoid muscles during early and late cocking phases of the throw, whereas the subscapularis and latissimus dorsi muscles were more active during the acceleration phase of the throw. They also identified that amateurs tend to utilize more of the rotator cuff muscles during the acceleration phase. This notion is further supported by a study of healthy, skilled throwers in which the EMG activity of the subscapularis muscle was lower during wind up, increased dramatically by late cocking, increased further during acceleration to 185% of test value, and tapered to 97% during follow-through.²⁰ Athletes with painful shoulders in the same study reached only one-third to one-half the normal values during the throwing motion.

Subscapularis muscle function has also been studied with other overhead sporting movements. During a tennis serve, the subscapularis muscle is most heavily recruited during late cocking and early acceleration.²¹ During the golf swing, subscapularis muscle activity tends to increase through acceleration in the dominant shoulder and tends to maintain a moderate level of activation throughout the swing in the nondominant shoulder.^{22,23} In EMG analysis of healthy freestyle swimmers, the subscapularis muscle remains at a constant level of significant activation throughout the stroke.²⁴ However, this pattern does not hold true for swimmers with a painful shoulder who exhibit an approximate 50% drop in subscapularis muscle activity during the recovery phase (the last phase of a freestyle stroke when the airborne arm is about to return to the water at the front of the body).²³ This drop in activity may be due to muscle inhibition from TrPs, or it could represent an attempt to avoid aggravation of painful TrPs during the extreme internal rotation and extension of this phase of the freestyle stroke.¹³

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in

one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 26-1 grossly represents the functional unit of the subscapularis muscle.¹³

Box 26-1 Functional unit of the subscapularis muscle

Action	Synergists	Antagonist
Shoulder internal rotation	Teres major Latissimus dorsi Pectoralis major	Infraspinatus Teres minor
Shoulder adduction	Teres major Latissimus dorsi Pectoralis major	Deltoid Supraspinatus

The subscapularis muscle also functions synergistically with the infraspinatus, teres minor, and supraspinatus muscles to stabilize the head of the humerus in the glenoid fossa during arm movements.^{7, 25}

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Subscapularis TrPs result in severe pain of the upper limb at rest and during motion.¹³ Pain is primarily referred to the posterior aspect of the shoulder (Figure 26-2). Spillover reference zones may extend over the scapula and down the posterior aspect of the arm to the elbow. A distal reference zone is sometimes present as a strap-like band of pain around the wrist with the dorsum of the wrist more painful than the volar aspect.²⁶ Although not reported in the classic Travell study, Jalil et al²⁷ provided a case study including two individuals who presented with atypical chest pain that responded to treatment (TrP injection) of subscapularis TrPs.

Figure 26-2. Referred pain pattern from TrPs in the right subscapularis muscle. The essential referred pain zone is solid red; the spillover zone is stippled red. Portions of the second through the fifth ribs have been removed for clarity.

3.2. Symptoms

The rotator cuff muscles are commonly involved in patients who report having shoulder pain. The subscapularis muscle is one of the most prevalent muscles found to have TrPs. Hidalgo-Lozano et al²⁸ found active TrPs in 42% of individuals diagnosed with shoulder impingement syndrome. During early stages of subscapularis myofascial dysfunction, patients demonstrate decreased function when reaching into abduction and external rotation (as if reaching back to throw a ball)¹³ or with reaching toward the rear of a vehicle from the front seat (as when soothing a crying child in her car seat). As the dysfunction progresses, lifting the arm becomes increasingly painful and difficult with abduction limited to 45° or less. The patient will likely describe pain at rest, pain with movement, and the inability to reach the opposite armpit (as when applying deodorant). Because of the severe pain and range of motion (ROM) limitations, the patient may be diagnosed with adhesive capsulitis or “frozen shoulder.” If presenting with referred pain at the wrist, the patient may complain of soreness in a strap-like area and may move a wristwatch or bracelet to the opposite hand. In mild cases of subscapularis TrP involvement, these authors have observed reports of “tightness” at the wrist upon maximal overhead reaching. Subscapularis muscle shortening due to the presence of TrPs may also contribute to subluxation of the head of the humerus. This concept is consistent with the observations of anatomic architecture of rotator cuff musculature by Ward et al⁸ who pointed out that the stabilizing function of these muscles is sensitive to length changes. Some patients will also describe snapping or clicking sounds around the shoulder joint with arm movements, which is usually associated with subscapularis and/or supraspinatus TrPs.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction assists in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper examination of the subscapularis muscle, the clinician should observe shoulder girdle posture, scapular position, and active and passive ROM of the shoulder girdle, paying close attention to muscle activation patterns and the scapulohumeral rhythm. The clinician should note when and where pain occurs. Subscapularis TrPs can produce pain at rest or during movement, particularly during arm elevation in the coronal plane and especially when combined with external rotation. The pain usually occurs throughout abduction ROM. Clinically, this muscle is seldom involved by itself but rather in association with the infraspinatus, supraspinatus, or the levator scapulae muscles, which also commonly have TrPs.

In order to identify TrPs in the subscapularis muscle that may be limiting ROM and thus influencing dysfunction, the clinician should identify limited ROM by performing specific ROM testing for all parts of the muscle. Because the patient with subscapularis TrPs often presents with major ROM limitations, a thorough examination of all contributing factors to the lost ROM should be completed. The clinician can expect external rotation to be restricted due to subscapularis TrPs, but must also consider that full elevation may be limited due to the prerequisite external rotation required to achieve full elevation (abduction or flexion).¹³ One helpful sign in determining subscapularis muscle restriction is greater loss of external rotation at 45° versus 90° of abduction.²⁹

Muscle-specific resisted testing should be carried out to identify impairments in muscle function and reproduction of painful symptoms. If active TrPs are present in the subscapularis muscle, resisted internal rotation at 45° abduction may be painfully limited.

The Apley's Scratch test (flexion, abduction, external rotation) is typically restricted by subscapularis TrPs. This version of the Apley's test requires full flexion, abduction, and external rotation of the arm at the glenohumeral joint and is performed by placing the hand of the affected side over the head and reaching as far toward the opposite scapula as possible (Figure 21-3B). If no dysfunction is present, the fingertips should reach to the opposite shoulder blade. This test stretches the shoulder adductors and the subscapularis muscle. When the range of these muscles is limited due to TrPs, the hand of the affected side may barely reach behind the head. This limitation is similar when the movement is performed actively or passively due to the impaired lengthening of the subscapularis muscle.

Accessory joint motion should be tested in the glenohumeral joint, acromioclavicular joint, sternoclavicular joint, and scapulothoracic joints. Many times joint hypomobility in the sternoclavicular joint can cause impairment in shoulder elevation contributing to alterations in the normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns contributing to overload of the subscapularis and other rotator cuff muscles.

Scapular and humeral head positions should be assessed at rest and during upper extremity elevation because malalignment can be a significant contributing factor to subscapularis muscle overload during upper extremity functional activities that require

combined internal rotation and adduction.

A general cervical screen, testing for neurologic signs, and neural mobility testing of the upper extremity should also be investigated to eliminate radicular symptoms as causative. If referred wrist pain is present, a clinical examination of local tissues at the wrist should also be conducted.

3.4. Trigger Point Examination

The patient should be positioned in supine with the arm abducted to 90° (if tissue tension allows) to expose the chest wall and axilla. Many patients with significant TrP activity such as those presenting with a diagnosis of adhesive capsulitis may be limited to only 20° to 30° of abduction. If sufficient abduction for examination is not available, the contract-relax technique may be used to achieve additional ROM.^{13,29,30} Before palpation, the relation to other structures should be considered: the subscapularis muscle constitutes much of the posterior axillary wall. Anterior to the subscapularis muscle is the serratus anterior (inferomedially) and the coracobrachialis muscles, the biceps brachii muscle, the axillary and subscapular vessels, and the brachial plexus (superolaterally). Posterior to the subscapularis muscle lies its attachment sites at the scapula and glenohumeral capsule. Inferiorly, the subscapularis muscle meets its synergists, the teres major and latissimus dorsi muscles (Figure 26-3).¹ The subscapularis muscle can exhibit TrPs in any portion of its muscle belly; however, secondary to its deep anatomic location, proper access to the different muscle fibers is difficult. The most easily accessed lateral site lies along axillary border of the scapula on its costal surface within the vertical fibers of the muscle; the second lateral site lies just superior to this among the more horizontally oriented fibers (Figure 26-2). Harrison et al³¹ identified common motor points within the horizontal fibers of the subscapularis muscle that aimed at developing a technique for botulinum toxin injection for neuromuscular blockade. The plotted motor points of 20 subscapularis muscle dissections are consistent with the common TrP sites described in the previous edition of this book.¹³

Figure 26-3. Relation of the subscapularis muscle (dark red) to the surrounding muscles (lighter red) when the scapula (shown as a vertical white line) has been pulled away from the chest wall by the clinician.

Adequate abduction of the scapula is also required to access the subscapularis muscle for manual palpation and may be achieved by maintaining traction on the humerus or when possible, by hooking the fingers of the nonpalpating hand along the vertebral border of the scapula and pulling it laterally (as shown by the arrow in Figure 26-4A).

Figure 26-4. Examination of the subscapularis muscle. A, The clinician grasps the vertebral border of the scapula and passively pulls it as far laterally as possible to expose the subscapularis muscle. B, Palpation of the subscapularis muscle.

While maintaining scapular abduction, the clinician then places the back part of the palpating hand against the rib cage and slowly sinks the tips of the fingers posteriorly to palpate the subscapularis muscle against the anterior surface of the scapula. Then, cross-fiber flat palpation over the surface of the scapula is used to identify TrPs (Figure 26-4B). In the inferior, more vertical fibers, this direction will be perpendicular to the longitudinal axis of the scapula and gradually transitions to an inferior-superior strumming as the moves superiorly in the muscle (note the fiber orientation in Figure 26-1). Although the entirety of the subscapularis muscle cannot be examined, the inferolateral site described above may be accessed by sliding the palpating finger toward the chest wall, such that the dorsum of the finger contacts the serratus anterior muscle and the subscapularis muscle fibers are felt beneath the finger (Figure 26-4B). The clinician may then move in a superior direction toward the coracoid process to assess the clinician more superior fibers. The medial subscapularis muscle fibers may be accessed along the vertebral border of the scapula with the patient in a prone or side-lying position. However, the thick layers of trapezius, rhomboid, and serratus anterior musculature through which the clinician must palpate make this a nonspecific assessment of the subscapularis muscle.

In the presence of a TrP, sustained light to moderate pressure will reproduce the patient's posterior shoulder and scapular pain, as well as, an occasional "twinge in the wrist."¹³ Local twitch responses may be visually observed but are more likely to be felt given the muscle's location. Although not essential to diagnosis, the local twitch response is strongly confirmatory. The axillary region and subscapularis muscle are sensitive areas for

many patients and may be exquisitely tender or ticklish with even light pressure in the presence of TrPs. Care should be taken (and fingernails kept short) to avoid confusion of skin pain.

Al-Shenqiti et al³² found good test–retest reliability of TrP detection in patients with rotator cuff tendonitis when the criteria of presence or absence of the taut band, spot tenderness, jump sign, and pain recognition were used.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the subscapularis muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.¹³

Subscapularis TrPs can be activated by activities involving repetitive exertion with forceful internal rotation such as freestyle swimming,^{24,34,35} throwing a baseball,^{20,36} or serving in tennis.^{21,37} Other movements that may activate subscapularis TrPs include repeated forceful overhead lifting while exerting strong adduction (as in swinging a child back and forth from between the legs to overhead or as in poorly performed kettle bell swings); sudden stress overload as in reaching back abruptly at the shoulder level to catch oneself when falling¹³; local traumatic injury such as glenohumeral dislocation, tear of the shoulder joint capsule, or proximal humeral fracture; prolonged immobilization of the shoulder in an adducted, internally rotated position; or surgical or medical procedures such as mastectomy, lumpectomy, or radiation treatment.^{38–40} Once established, these TrPs may be perpetuated by repetitive movements requiring internal rotation or typical poor “slumped” posture fostering prolonged positioning in internal rotation of the humerus.

4.2. Associated Trigger Points

Associated TrPs can develop in the muscles within the referred pain areas resultant from an active TrP.⁴¹ Therefore, muscles in the referred pain areas for each muscle should also be considered for examination. Pain referral from subscapularis TrPs could activate TrPs in the deltoid, infraspinatus, supraspinatus, triceps brachii, teres major and minor, and latissimus dorsi muscles. When TrPs are present in the subscapularis muscle, arm movement may be significantly restricted without associated TrP activity in other shoulder girdle muscles. Once the TrPs become active, further pain-induced movement restriction becomes severe such that functionally related muscles develop TrPs. Ultimately, motion at the shoulder may be “frozen” and mimic adhesive capsulitis (see Chapter 33 for more on this diagnosis). Often the pectoralis major muscle first develops associated TrPs, followed by teres major, latissimus dorsi, and the long head of the triceps brachii muscles. Finally the anterior deltoid muscle becomes involved. Once TrPs occur in all these muscles, their

combined shortened lengths may severely limit all movement of the shoulder, mimicking the medical diagnosis of adhesive capsulitis.⁴²

4.3. Associated Pathology

Cervical radicular pain or radiculopathy in the C5 or C6 nerve roots often results in the formation of TrPs in those muscles innervated by the same nerve roots. Oftentimes patients with C5-6 radiculitis describe deep anterior shoulder pain, anterolateral shoulder pain, brachium and forearm pain, and pain into the radial aspect of the hand and lateral digits. Patients with C7 radicular symptoms will often describe having pain in the shoulder, arm, and the dorsal aspect of the wrist which is part of the referral pattern from subscapularis TrPs.

Other diagnoses to consider include cervical arthritis or spurs with nerve root irritation and brachial plexus injuries. All of these neurogenic sources of pain are likely to exhibit EMG evidence of denervation (positive sharp waves and fibrillation potentials) in the muscles supplied by the compromised nerves.

Although further research is warranted in all cases to better understand their relationships, subscapularis TrPs are closely associated with subacromial pain syndrome; primary and secondary FSS⁴³; rotator cuff pathology; C5, C6, or C7 radicular pain/radiculopathy; thoracic outlet syndrome; and scapulothoracic or subacromial bursitis, which can cause similar pain that is not due to subscapularis TrPs. Subscapularis and other rotator cuff muscle TrPs may be present with any of these conditions and can also mimic these conditions, which are further discussed in Chapter 33.

FSS or adhesive capsulitis has been defined by the American Elbow and Shoulder Surgeons as “a condition of uncertain etiology characterized by significant restriction of both active and passive shoulder motion that occurs in the absence of a known intrinsic shoulder disorder.”⁴³ The diagnosis, FSS or adhesive capsulitis, may be the result of other shoulder pathology or systemic disease or may be idiopathic in the case of primary FSS or adhesive capsulitis. Secondary FSS is typically related to an event that can be described by the patient.⁴³ The symptoms of subscapularis TrPs, including pain and significant limitations in external rotation and abduction, are similar to those associated with FSS. Myofascial dysfunction resulting from subscapularis TrPs should certainly be considered as a potential cause of pain and impairment in any patient presenting with a diagnosis of FSS. Given the ambiguous etiology of primary FSS, clinicians may question the potential for subscapularis TrP involvement in its development. Interestingly, thyroid disease, which is considered a systemic cause of secondary FSS, is also a systemic perpetuating factor of TrPs.¹³ In fact, there is only one case report describing the clinical reasoning behind the use of TrP dry needling in the treatment of an individual with adhesive capsulitis.⁴⁴ This case report describes a rapid improvement in pain and ROM following the initiation of dry needling applied to upper trapezius, levator scapulae, deltoid, and infraspinatus muscles. Surprisingly, there is no mention of subscapularis TrPs in this case report. Trigger point contribution to FSS is further discussed in Chapter 33.

Investigators have looked at the prevalence of TrPs, pain pressure threshold (PPT), and reproduction of shoulder pain in patients with a diagnosis of SIS.^{28,45,46} Investigators²⁸ assessed 12 patients and 10 matched controls for the prevalence of TrPs and PPT. The inclusion criteria was pain of greater than 3 month duration, pain greater than 4/10 with shoulder elevation, and a positive Neer and Hawkin's impingement test. Patients with SIS had a greater number of active and latent TrPs. The greatest prevalence of active TrPs was found in the subscapularis (42%), infraspinatus (42%), and supraspinatus muscles (62%). Decreased PPT in patients with SIS was directly correlated with the number of TrPs present. Patients who experienced reproduction of their pain with TrP palpation had significantly decreased PPT. Each patient with SIS had up to three active TrPs. The greater number of TrPs present, the lower the PPT. The results of this study lend credence to the theory that both peripheral and central pain mechanisms contribute to the pain experience of patients with SIS.²⁸

The presence of TrPs in 10 muscles was investigated in 27 patients with a diagnosis of SIS and 20 matched controls.⁴⁶ The number of muscles with TrPs was significantly greater in the SIS group as compared with the control group with the subscapularis, infraspinatus, and trapezius muscles having a significant number of active and latent TrPs. The infraspinatus muscle had the highest prevalence of active TrPs in the SIS group. The greater prevalence of TrPs in the SIS group adds relevance to the contribution of myofascial pain in the signs and symptoms of SIS.⁴⁶

In patients presenting with unilateral shoulder pain and a diagnosis of SIS with associated positive impingement tests, it is essential to examine neck and shoulder muscles bilaterally for the presence of both active and latent TrPs.

A number of studies implicate subscapularis TrPs in individuals with hemiplegia-related shoulder pain. Dysfunction often attributed to spasticity may actually be a result of subscapularis TrPs.⁴⁷ Diloranzo et al⁴⁷ published the results of a trial in which TrP dry needling was used in conjunction with standard rehabilitative therapy to improve pain and functional outcomes in individuals with hemiparetic shoulder pain syndrome (hemiplegia-related shoulder pain). More recently, Mendigutía-Gómez et al⁴⁸ observed that dry needling applied to shoulder muscles, including the subscapularis muscle, was effective for reducing pressure pain sensitivity and spasticity in patients who have had a stroke.

Scapulohumeral muscle imbalances, more commonly referred to as scapular dyskinesia, are defined as an alteration of normal motor recruitment patterns of muscle contractions of the shoulder girdle musculature during upper extremity movements. This alteration of muscle recruitment can lead to incoordination, early fatigue, and overloading of the rotator cuff muscles and must be assessed and treated for the effective resolution of shoulder pain due to shoulder girdle TrPs.

5. CORRECTIVE ACTIONS

The patient should avoid habitual, sustained, or repetitive motions that overload the subscapularis muscle, such as retrieving heavy objects from a high shelf and lifting heavy

objects from the floor. Reaching up to fasten the seatbelt when it is on the same side as the affected arm can be quite painful and challenging. During the acute phase, the unaffected arm should be utilized to fasten the seatbelt.

Attaining restful sleep may be difficult due to the inability to assume comfortable sleeping positions for prolonged periods. The individual with subscapularis TrPs may be most comfortable sleeping on the back or pain-free side. When the patient lies on the uninvolved side, sleep is improved by supporting the uppermost elbow and forearm (painful limb) on a bed pillow (Figure 22-4A) avoiding prolonged shortening of the affected subscapularis muscle that can cause referred pain. This technique can also be used to keep the arm in a neutral position when lying supine (Figure 22-4B) or when seated (Figure 22-4C). Another option is to place the pillow under the arm perpendicular to the body keeping the arm out of adduction and internal rotation and in a resting length-tension position for the subscapularis muscle. Patients should be cautioned regarding lying in bed with their arm(s) above their head in an abducted and externally rotated position because this posture will keep the subscapularis muscle in a prolonged lengthened position.

During waking hours, the individual with subscapularis TrPs should be careful to avoid forward head and rounded shoulder postures, which are typically adopted during seated desk and computer work, texting, and driving. Setting an alarm every half hour to cue frequent standing, stretching, and arm movement can be beneficial in preventing the arm from remaining too close to the side for prolonged periods. When driving long distances, using the armrest or placing a small towel roll in the axilla may allow the arm to rest in some abduction (preventing full shortening). Stretches of the arm up and behind the head, or across to behind the opposite seat or headrest, can be helpful.

When prescribing neuromuscular reeducation or therapeutic exercises early in a supervised rehabilitation program, research supports utilization of supported vertical and diagonal wall slides, which decrease loading of the rotator cuff muscles.^{49,50} As pain decreases and ROM increases, the addition of exercises that target the subscapularis muscle should be added. These exercises include internal rotation at 0° and 90° abduction, scapular punch, a diagonal movement pattern simulating throwing acceleration, high row, low row, dynamic hug, and push up plus. These exercises produce a muscle activation ranging from 20% to 136% MVC.^{5,36,49}

The patient may inactivate subscapularis TrPs with the application of self-pressure release of TrPs in seated, standing, and/or lying positions. In the seated position, hanging the affected arm down between the legs is desired when motion in abduction is extremely painful and ROM is limited (Figure 26-5A). Most of the subscapularis muscle is accessible from this position. In the seated position, the affected arm is raised to allow improved access to the subscapularis muscle (Figure 26-5B). The fingertips or thumb of the opposite hand are placed inside the edge of the shoulder blade and pressed back into the subscapularis muscle. Placing the affected arm's hand on the opposite shoulder, if possible, brings the shoulder blade around the side of the body and can improve access (Figure 26-5C). This technique can also be employed supine if the seated position is too painful or not tolerated well (Figure 26-5D). If the shoulder is too acute, a towel roll can be placed under

the arm instead of reaching the affected arm across the body (Figure 26-5E). The tenderest spot should be identified and pressure held for 30 seconds until pain subsides. This technique can be repeated up to 5 times. Massage across the taut bands in the same position may also be effective for symptom relief.⁵¹

Figure 26-5. Self-pressure release of TrPs in the subscapularis muscle. A, Seated position for an acutely painful shoulder. B, Starting position for self-pressure release of TrPs in the subscapularis muscle. C, Placing hand on opposite shoulder improves accessibility to the muscle. D, Supine option. E, Supine option for acutely painful shoulder.

A patient can learn to release tightness in the subscapularis muscle by slowly and firmly stretching it using the middle hand positions in the doorway, stretching into external rotation (Figure 26-6). A firm, gentle, pain-free stretch can be held for 30 seconds and repeated up to 3 to 5 times. To augment the stretch, a PNF hold relax technique can be used. The patient gently pushes into the door frame (internal rotation) to minimally contract the subscapularis muscle for 5 to 10 seconds followed by relaxation and gentle stretching of the muscle into further external rotation by rotating the body away from the doorframe. Alternatively, the stretch can be augmented through respiration by timing the inhale with a gentle push into the doorframe and the exhale with a gentle stretch further

into external rotation by rotating the body away from the door frame. This sequence can be repeated 3 to 5 times, up to 3 to 4 times per day. A cold pack may be of therapeutic benefit immediately following pressure release or stretching, especially in the case of acute shoulder pain.

Figure 26-6. Self-stretch of the subscapularis muscle in a doorway with a towel placed in the axilla for optimal alignment.

It is imperative that any glenohumeral posterior joint tightness be addressed, in addition to restoration of efficient shoulder girdle mechanics, while concomitantly treating TrPs in the supraspinatus muscle. Treatment isolated to TrPs in the supraspinatus muscle that does not address the shoulder joint will result only in temporary relief of pain arising from TrPs in the supraspinatus muscle and may warrant further assessment.

Rhomboid Minor and Major Muscles

“Shoulder Blade Sorcerers”

Matthew Vraa

1. INTRODUCTION

The rhomboid minor and major muscles are important stabilizers of the scapula. The rhomboid minor muscle originates from the distal ligamentum nuchae and the spinous processes of C7 and T1 and descends inferolaterally to the base of the triangular medial surface of the spine of the scapula. The rhomboid major muscle originates from the spinous processes and supraspinous ligaments of T2-T5 and descends inferolaterally to the medial border of the scapula between the root of the scapular spine and the inferior angle. The muscles are innervated by a branch of the dorsal scapular nerve. Functionally, the muscles are involved in scapular retraction, downward (internal) rotation, and components of scapular elevation. They also provide dynamic stabilization during lifting, pushing, and pulling as well as activities of daily living tasks such as styling hair, tucking in a shirt, putting on a seat belt, and picking up a workbag. The referred pain from rhomboid trigger points (TrPs) expands over the medial border of the scapula and spreads superolaterally over the supraspinatus muscle and spine of the scapula. Trigger points in the rhomboid muscles have been associated with upper quarter myofascial pain syndrome and reduced upper extremity strength. Trigger points in these muscles can be activated or perpetuated by prolonged poor posture, holding the arms overhead for extended periods of time, or structural causes such as scoliosis or leg length discrepancies. The rhomboid muscles are involved in pain syndromes of the cervical spine, particularly cervical radicular pain. Individuals with space-occupying lesions at C4-C5, C5-C6, or C6-C7 commonly present with TrPs in the rhomboid muscles. Additionally, dorsal scapular nerve entrapment, thoracic facet syndrome, and costovertebral joint dysfunction can present with a pain pattern (interscapular pain) similar to rhomboid muscle TrPs and must be considered in the differential diagnosis. Corrective actions include TrP self-pressure release and correcting abnormal postures during sitting (especially driving and deskwork) to decrease excessive loading of the rhomboid muscles in a prolonged lengthened position.

2. ANATOMIC CONSIDERATIONS

Rhomboid Minor

The rhomboid minor muscle originates from the distal ligamentum nuchae and the spinous processes of C7 and T1.¹ The muscle descends inferolaterally to the base of the triangular medial surface of the spine of the scapula. The rhomboid minor muscle sits just inferior to the levator scapula muscle attachment on the scapula.¹ The rhomboid minor muscle can have attachments of the ligamentum nuchae of C4-C6.²

Rhomboid Major

The rhomboid major muscle originates from the spinous processes and supraspinous ligaments of T2-T5.¹ The quadrilateral sheet of the muscle descends inferolaterally to the medial border of the scapula between the foot of the spine and the inferior angle (Figure 27-1). A case study of a 49-year-old Korean male demonstrated a trapezoid-shaped rhomboid major muscle with different attachments on the right and left sides.² The muscle attached superiorly to the ligamentum nuchae at C6, extending to the spinous process of T2 on the right and to T4 on the left.²

Figure 27-1. Attachments of the rhomboid minor and major muscles to the vertebral spinous processes and the medial border of the scapula, showing the direction and extent of the muscle fibers.

Rhomboid Tertius

Although there is little anatomic variation of the rhomboid major and minor muscles, there are documented cases of a third rhomboid muscle (tertius). In one case, the muscle originated from the spinous processes of T6-T8 on the left side and from T6 to T7 on the right with muscle fibers running nearly horizontally as it inserted into the most inferior part of the medial border of the scapula.³ The maximal width was noted at 40 mm on the left side and 27 mm on the right.³

Another documented case of the rhomboid tertius muscle noted the inferior origin as the spinous process of T5 bilaterally. However, the superior border was T4 spinous process on the left and T2 spinous process on the right.² The insertion was similar bilaterally to the other rhomboid tertius muscle variation with an attachment to the inferior medial border of the scapula.^{2,3}

Rhomboid Interdigitating

Other variations exist with slips of the surrounding muscles (teres major, latissimus dorsi, and serratus anterior) interdigitating into rhomboid muscles.³ This variation is unlikely to alter the function of the rhomboid major or minor muscles.

2.1. Innervation and Vascularization

The rhomboid minor and major muscles are innervated by a branch of the dorsal scapular nerve.¹ This nerve originates from the C4-C5 nerve root and becomes the dorsal scapular nerve via the upper trunk of the brachial plexus.⁴⁻⁶ The nerve can also originate from the C6 root and pierce the middle scalene muscle as it passes the vertebral border of the scapula between the serratus posterior superior, posterior scalene, and levator scapulae muscles to innervate the rhomboid muscles.⁷ The dorsal scapular nerve also innervates the levator scapulae muscle.

Vascular supply of the rhomboid minor and major muscles is variable. The dorsal scapular artery or a deep branch of the transverse cervical artery typically supplies the muscles.¹ The dorsal branches from the posterior intercostal arteries can also supply the rhomboid muscles.¹

2.2. Function

The rhomboid muscles adduct and elevate the scapula.^{1,4,5,8} The attachment of the rhomboid major muscle fibers to the lower vertebral border of the scapula tends to downwardly rotate the scapula causing the glenoid fossa to tilt inferiorly.^{1,4,5,8} Both

rhomboid muscles assist in shoulder abduction, adduction, flexion, extension, and scaption motions of the arm by stabilizing the scapula in the retracted position.^{1, 4, 5, 8-13}

No distinction in function has been noted between the rhomboid minor and major muscles. Because of the differences in attachments of both muscles to the scapula, the rotation effect of the rhomboid major muscle may be much greater than that of the minor. However, because the majority of electromyography (EMG) studies conducted on the rhomboid muscles only studied the rhomboid major muscle, it is difficult to make a definitive statement regarding individual functions of each muscle.

EMG data demonstrate that the rhomboid major muscle is active to varying degrees in just about all upper extremity activities. The rhomboid muscles are more active during shoulder abduction, circumduction, and scapular elevation than during glenohumeral flexion or extension.^{14, 15} Ito¹⁶ noted that the rhomboid muscles exhibited steadily increasing activity throughout abduction and similarly during flexion, but in the latter case, the EMG activity reached only about two-thirds of the amplitude seen with abduction. In another study, the electrical activity of the rhomboid muscles rapidly increased in intensity between 160° and 180° of abduction and flexion.¹⁷ This activity was not predicted by any of the aforementioned anatomic-based actions. The increase may be due to the stabilization actions that the rhomboid muscles provide during upper extremity activities. Wickham et al¹⁸ found maximal voluntary isometric contraction (MVIC) in shoulder abduction between 90° and 135° but less activity upon lowering the arm from the maximal abducted position. Castelein et al¹⁰ showed MVIC activity at 135° of flexion against a downward force applied at the elbow. The results of the MVIC testing were not statistically different in a prone horizontal abduction test position versus a prone position against resistance with the arm in an overhead position (similar to the position to test lower trapezius muscle strength).¹⁰

The rhomboid muscles are active in both forward and backward swings of the arm during walking, probably to stabilize the scapula.¹⁵ Although the strength of adduction and extension of the humerus is diminished by loss of rhomboid muscle fixation of the scapula, ordinary function of the arm is affected less by loss of rhomboid muscle fixation of the scapula than by loss of either the trapezius or the serratus anterior muscles.⁴

EMG activity has been examined in some sport activities. During overhead baseball pitching, MVIC activity of the rhomboid muscles was highest during the acceleration and deceleration phases of throwing mechanics.¹⁹ Similar high MVIC activity is recorded during the acceleration phase of the windmill softball pitch.²⁰ The rhomboid muscles were most active during the start of the forward golf swing followed by the acceleration phase (hitting the golf ball).¹⁹

Scovazzo et al²¹ compared fine wire EMG recordings of rhomboid muscle activity during aquatic swimming between 14 subjects with a painful shoulder and 12 subjects with pain-free shoulders. EMG activity in painful shoulders was only one-fourth that in normal subjects. But during middle pull-through, it was 4 times that of normal, falling back to less than normal throughout early recovery.²¹ The initial pattern of inhibition could be

expected because this muscle is prone to inhibition and weakness.²² However, the subsequent abnormally high level of rhomboid muscle activity is surprising and is more characteristic of a muscle that is strongly compensating for the dysfunction of another muscle. Identification of which muscles had TrPs and which muscles were free of TrPs would be invaluable in a study of this type.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 27-1 grossly represents the functional unit of the rhomboid minor and major muscles.²³

Box 27-1 Functional unit of the rhomboid minor and major muscles

Action	Synergists	Antagonists
Scapular elevation	Levator scapulae Upper trapezius	Latissimus dorsi Lower trapezius Pectoralis minor
Scapular retraction	Middle trapezius Latissimus dorsi	Serratus anterior Pectoralis major Pectoralis minor
Scapular downward rotation	Levator scapulae Latissimus dorsi	Upper trapezius Lower trapezius Serratus anterior

It should be noted that the fasciae of the rhomboid minor muscle and the serratus anterior muscle are interdigitated.¹ This relationship is the main reason these muscles are clinically correlated in dysfunction.

During the initiation of upper extremity glenohumeral flexion, the action of downward rotation by the levator scapulae and the rhomboid muscles is dominant over the action of upward rotation by the upper trapezius and the serratus anterior muscles.²⁴ This stabilization of the scapula then allows for scapular upward rotation during later stages of glenohumeral flexion and abduction.^{8,25,26} A length deficit in the rhomboid muscles and/or the levator scapulae muscle can cause movement impairments during scapular upward rotation. If the glenohumeral joint does not compensate for the deficient scapular

motion, shoulder flexion or abduction range of motion will be limited.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the rhomboid muscles usually refer pain to the vertebral border of the scapula between the scapula and the paraspinal muscles (Figure 27-2). This interscapular pain can project laterally and superiorly over the supraspinatus muscle and the spine of the scapula on the affected side.²³ Experimental injection of hypertonic saline into normal rhomboid muscles caused referred pain felt over the medial part of the scapula, extending upward and laterally over to the acromion.²⁷

Figure 27-2. Composite referred pain pattern (essential zone solid red, spillover zone stippled red) caused by TrPs of the right rhomboid muscles.

The pain pattern somewhat resembles that of the levator scapulae or the scalene muscles but without the cervical component and without loss of motion in rotation or side bending in the neck. Part of the pain pattern can also mimic that of the supraspinatus, infraspinatus, middle trapezius, latissimus dorsi, and serratus posterior superior muscles, but these muscles typically have a pain that refers beyond the acromion or down into the upper extremity.²³ Referred pain extending to the arm is not a feature of TrPs in the rhomboid muscles.

3.2. Symptoms

Patients with TrPs in the rhomboid muscles will typically report a superficial aching pain along the medial border of the scapula between the shoulder blade and the spine that is present at rest and unaffected by normal movements. Patients may report trying to attempt to rub the area of pain for relief. Often, the patient reports soliciting a loved one to “rub it out” or that they have leaned against the corner of a wall to apply pressure to the area. Patients may also report snapping and crunching feelings during movement of the scapula, which may be due to TrPs in the rhomboid muscles. The skin overlying the area of reported pain may even be bruised or discolored if the patient has repeatedly been applying firm pressure in attempts to relieve the pain.

A retracted position of the shoulder girdle is commonly associated with muscle facilitation dysfunctions of the scapular retractors (trapezius muscle, levator scapula muscle, and latissimus dorsi muscles). A protracted position with rounded shoulder posture can be associated with facilitated/adaptive shortening of the serratus anterior and/or pectoralis muscles (major and minor).^{24,28} In this protracted position, facilitated upper trapezius and levator scapulae muscles are common.^{24,28} This pattern is often clinically correlated with muscle inhibition of the rhomboid and middle and lower trapezius muscles.²⁸ This overstretch/inhibition pain from a protracted scapular position will gradually subside if the muscle remains in a neutral length tension position that places it neither under tension nor in a shortened position.⁴

The lack of literature related to TrPs in the rhomboid muscles may be due to the fact that the rhomboid TrPs are less common than other shoulder girdle muscles.^{29–32} Trigger points in the rhomboid muscle are often associated with other impairments and upper quarter conditions.^{30–33} Pain is rarely identified as originating in these muscles until TrPs in neighboring affected muscles (such as the levator scapulae, supraspinatus, infraspinatus, middle trapezius, and the serratus posterior superior muscles) have been deactivated.

In a case study by Kellgren in 1938, an individual presented with TrPs as he described in the rhomboid muscles. The TrPs presented ipsilateral interscapular pain with referred pain that was reported from the base of the head, along the upper trapezius muscle down to the acromion on the affected side.²⁷ Upon injections of the TrPs with 16 mL of novocaine, the left-sided neck and interscapular pain of 6 months’ duration was fully resolved within 1 week.²⁷

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. A static posture analysis provides a wealth of information regarding the length-tension relationships of scapular muscles and their relationship to the resting position of the scapula. A rounded shoulder posture may indicate shortening and tightness of the pectoralis major and minor muscles and can put sustained stretch on the rhomboid and middle trapezius muscle fibers. Tightness of the latissimus

dorsi muscle can lead to increased internal rotation of the humerus, causing an appearance of a forward shoulder position. Postural scapular elevation can be caused by facilitation of the levator scapula and upper trapezius muscles and inhibition of the lower trapezius muscle. Scapular winging is often associated with inhibition or weakness of the serratus anterior muscle.²⁴ Refer to Chapter 76 for more on posture.

After a comprehensive postural screen of the upper and lower quadrants, a movement screen of the shoulder girdle and upper extremity should be performed to identify movement impairments that need to be examined more closely.^{4,34} Active and passive range of motion of the shoulder girdle complex should be thoroughly examined with specific observation of scapular motion. Clinicians should also screen the cervical, thoracic, and lumbar spine for mobility impairments as well as the scapulothoracic, glenohumeral, acromioclavicular, sternoclavicular, and elbow joints.³⁴ Impairments in any of the aforementioned joints can directly or indirectly affect rhomboid muscles' activation patterns or those of its functional unit. Examination of these joints may help to identify soft tissue, muscular, or accessory motion limitations.^{4,5,24,34}

Additionally, clinical screening for proper resting and contracted muscle length may reveal muscle facilitation/inhibition patterns (including the rhomboid muscles) that need to be addressed.^{4,5,24,34,35}

Although no research currently exists to describe the relationship of upper quarter movement impairments and rhomboid TrPs, it is expected that biomechanical faults may occur with rhomboid muscle dysfunction. Inefficient strength and length of the rhomboid muscles do alter movement patterns of the scapula and the upper extremity.^{35–38} Furthermore, TrPs in other shoulder girdle muscles affect movement patterns and shoulder pain.^{38–43} Assessing the scapulothoracic rhythm during upper extremity flexion and abduction may provide useful information on muscle function and performance.

Passive range of motion of the joints of the upper quarter can aid in the differentiation of soft tissue dysfunction versus faulty joint mechanics.^{24,34} Assessing the mobility of the scapula in elevation, depression, protraction, retraction, and rotation can be achieved by manual assessment. This assessment of the scapula for mobility over the thoracic cage can reveal the source of movement restrictions. Restrictions in upward rotation or protraction implicate the rhomboid or levator scapulae muscles. Difficulty with retraction could be caused by a length deficit in anterior structures (pectoralis major/minor muscles), whereas the inability to depress the scapula would implicate the levator scapulae and upper trapezius muscles. Length deficits of the latissimus dorsi and lower fibers of the trapezius muscles could cause restriction of scapular elevation. Some patients may report, or the clinician may palpate, snapping and crepitus during mobility assessment of the scapula, and these phenomena may be due to TrPs in the rhomboid muscles.

Additional testing should include muscle length examination in abduction and adduction.^{4,5,24,34} Classic muscle testing of the rhomboid muscles involves prone position of the patient with horizontal adduction scapula being tested.^{4,5} Typically, differentiation for middle trapezius muscle versus rhomboid muscle is determined by the testing position:

the arm in a externally rotated position for the trapezius muscle and the arm internally rotated for the rhomboid muscles.^{4,5}

The most reliable clinical indication of rhomboid major weakness is obtained by palpation of the rhomboid major muscle during adduction and elevation of the scapula with downward rotation of the scapula. Muscle fiber orientation along with depth will aid in differentiation between muscle activation of the middle trapezius muscle and the rhomboid muscles.

3.4. Trigger Point Examination

Cross-fiber flat palpation is preferred to identify taut bands and TrPs in the rhomboid minor and major muscles with the patient in the prone position (Figure 27-3). The muscle can also be palpated with the patient in the seated position, with the arm supported in 90° elevation in the sagittal plane or with the arm in the hammerlock position. A TrP within a taut band of the rhomboid muscle can be distinguished from the overlying trapezius muscle by fiber orientation. The rhomboid muscle fibers are directed obliquely, in an inferolateral direction away from the vertebrae; the lower trapezius muscle fibers are angled superolaterally, and the middle trapezius muscle fibers run relatively horizontally.

Figure 27-3. Palpation of the rhomboid muscles in prone.

To define the precise borders of these muscles, the patient should lie prone or sit with his or her hand resting on the lumbar spine (hammerlock position). This position will raise the vertebral boarder of the scapula off the thoracic cage. The clinician can then place a finger (reinforced with the opposite hand, if necessary) deep to the medial border of the scapula. When the patient lifts the hand up off the back, the rhomboid muscles contract vigorously, pushing the clinician's finger out from under the scapula. Once the rhomboid

muscles have been outlined, deep cross-fiber flat palpation along the rhomboid muscle fibers can be used to identify any taut bands that contain TrPs (Figure 27-4).

Figure 27-4. Differentiation of rhomboid muscles in the seated posture with the arm in the hammerlock position.

The rhomboid muscles are examined for taut bands along the entire muscle with a cross-fiber flat palpation. Trigger points can be anywhere along the length of the taut band

and anywhere within the muscle. All but the caudal ends of the lowermost fibers of the rhomboid major muscle will be palpable through the trapezius muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the rhomboid muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁴⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. Therefore, it is essential to examine workloads, strength, and length of other upper extremity and scapular stabilizing muscles.

Trigger points in the rhomboid muscles may be activated by holding the arm in abduction or flexion above 90° for a prolonged period, such as when painting overhead, installing drywall, or with certain sport/recreational activities (rock climbing, volleyball, tennis, throwing sports, etc.). Trigger points can also be activated and perpetuated by working at a desk with a rounded shoulder posture and prolonged forward leaning. These positions are common with poor office workstation ergonomics and using handheld electronic devices, respectively.

Even when postural and behavioral corrections are made, some individuals may present with TrPs due to structural causes. A prolonged stretch due to prominence of the scapula on the convex side in upper thoracic scoliosis can create a structural dilemma. Adaptation in length can occur after certain disease process or injuries to the patient (congenital elevation of the scapula, cerebrovascular accident, accessory nerve disorder, brachial plexus injury). Other events and circumstances, like chest surgery or a limb-length discrepancy in the upper or lower extremity, can cause changes in how the upper extremity is held or used and can perpetuate TrPs in the rhomboid muscles.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by other TrPs⁴⁵; therefore, muscles in the referred pain areas for each muscle should also be considered. Several muscles refer pain in a similar pattern to that of the rhomboid muscles, including the scalene, levator scapulae, middle trapezius, infraspinatus, supraspinatus, serratus posterior superior, and latissimus dorsi muscles. These muscles should also be examined for the presence of TrPs, especially if the therapeutic response to rhomboid muscle treatment does not resolve pain. The anatomic proximity of the splenius capitis, splenius cervicis, spinalis muscle, longissimus, and iliocostalis muscles should also be evaluated for muscle dysfunction in the midthoracic region. Occasionally, rhomboid TrPs become obvious only after inactivation of TrPs in the scalene, levator scapulae, middle trapezius, infraspinatus, or supraspinatus muscles.

Patients with rhomboid TrPs frequently present with a rounded shoulder posture and are unable to achieve effective postural alignment due to tightness and TrPs in the pectoralis major and/or minor muscles. The rhomboid and middle trapezius muscles are then placed on prolonged stretch or experience overload as a consequence of the shortened pectoral muscles. This maladaptive position can perpetuate TrPs and muscle inhibition in both muscle groups, exacerbating the rounded shoulder position. Trigger points in the serratus anterior muscle can also contribute to rhomboid muscle overload.

4.3. Associated Pathology

Trigger points in the rhomboid muscles may be associated with, and can mimic, many different conditions. A thorough medical screening and physical examination are essential, and referral to another healthcare practitioner may be necessary. Systemic conditions from cardiopulmonary, gastrointestinal (upper portions), renal, hepatic, and biliary systems all have the potential to refer pain to the same anatomic location and pain referral areas as the rhomboid muscles.^{46–48} A systems review and review of systems (heart rate, blood pressure, respiratory rate, oxygen saturation, etc.) can aid in clinical reasoning.^{34, 46–48}

Due to the attachment sites and the innervation of the rhomboids muscles, articular or neural involvement may be associated with impairments in the rhomboid muscle function. Trigger points in the rhomboid muscles are often associated with other impairments or upper quarter conditions.^{30–33} Hsueh et al³³ observed that individuals with neural involvement at C4-C5, C5-C6, or C6-C7 can present with TrPs in the rhomboid muscles. There is additional evidence to support the role of scapular mobility in subjects with neck pain.^{10, 49–52} These studies recommend evaluating and treating using a regional impairment-based approach.^{53, 54} Refer to other texts for descriptions of manual therapy and exercises to address thoracic spine or rib cage dysfunctions that can perpetuate TrPs in the rhomboid muscles.^{55–59}

Articular dysfunction of spinal segments from C7 to T5 is associated with rhomboid TrPs. Usually two or more segments are involved. Occasionally, a T3 spinal segmental dysfunction of extension as well as ipsilateral lateral flexion and rotation is noted. This single-segment fault usually presents as reduced upper thoracic kyphosis with limited flexion mobility and concurrent scapular adduction with rhomboid muscle involvement. This segmental dysfunction must be recognized and appropriately treated. Concurrent rhomboid TrP deactivation often occurs with correction of this articular dysfunction.

5. CORRECTIVE ACTIONS

A patient with rhomboid TrPs should modify or limit any activity that involves holding the arm above shoulder height for a prolonged period, such as when painting or working overhead, and certain sport/recreational activities such as rock climbing. The use of a lumbar pillow or a thoracolumbar support may help to correct a rounded shoulder posture and place the muscles in a neutral length-tension position, especially while working at a desk or driving a car.

Patients should avoid any chair that pushes the upper torso, shoulders, and head/neck forward. Some backward slope of the backrest with lumbar support is needed for a comfortable and effective seated posture. When evaluating sitting posture at a desk, consideration of table height, keyboards, and computer screen distance/height to optimize ergonomic support (see Chapter 76).

For a patient who becomes preoccupied at a desk and forgets to take frequent breaks to change position and thus relieve the strain on the muscles, an interval timer can be placed across the room and set to ring every 20 to 30 minutes. This aid will promote intermittent movement, encouraging the patient to get up at regular intervals to reset the timer.

Scapular protraction, or any other observed faulty scapular position, due to functional scoliosis caused by a leg length discrepancy or an asymmetric pelvis, can be corrected by leveling the pelvis and straightening the spine with appropriate lifts in standing or sitting. Several options are available to address these structural asymmetries to normalize posture.

The patient should be cognizant of posture at work and during sleep for successful management of TrPs in the rhomboid muscles. Once local strength of the muscle is improved, addressing controlled and functional dynamic stability of the scapula will be important for successful return to sport.

Rarely do the rhomboid muscles need active stretching exercises. However, their antagonists, the pectoralis major and minor muscles, are often tight or shortened. Stretching the pectoral muscles, if shortened or tight, will assist in the maintenance of proper posture by placing the scapula in a better resting position, thus decreasing stretch tension on the rhomboid muscles (see Figs. 42-10, 11 and Fig. 44-6).

Additionally, the patient can treat the rhomboid muscles with pressure release by utilizing instrument-assisted techniques. Inexpensive options like laying on tennis balls (Figure 27-5A) or a rolled up towel are often effective. The patient can lie on the tennis ball and position the body and shoulder blade so the ball is over the TrP. The patient can locate each rhomboid TrP by rolling a single tennis ball along the medial border of the scapula. If there is involvement of both rhomboid muscles on one side, a pair of tennis balls can be used (Figure 27-5B). The pressure is centered on the most tender spot until the tenderness fades, usually holding firm pressure for 15 to 30 seconds and repeated as necessary. Other options include commercially available TrP self-release tools (Figure 27-6).

Figure 27-5. Rhomboid muscle self-pressure release of TrPs utilizing A, one tennis ball; B,

two tennis balls.

Figure 27-6. Rhomboid TrP self-release with TrP self-release tool.

Deltoid Muscle

“Overt Botherer”

Joseph M. Donnelly and Leigh E. Palubinskas

1. INTRODUCTION

The deltoid muscle consists of three parts that together form the rounded shape of the shoulder area. The anterior deltoid portion originates from the anterior border and superior surface of the lateral one-third of the clavicle. The middle deltoid portion originates from the lateral margin and superior surface of the acromion. The posterior deltoid portion originates from the lower edge of the crest of the spine of the scapula. All three portions insert onto the deltoid tubercle of the humerus. The deltoid muscle is innervated by the axillary nerve. The anterior, middle, and posterior deltoid portions can function individually or in conjunction with one another to perform motion at the glenohumeral joint. Simultaneous contraction of the anterior, middle, and posterior parts of the deltoid muscle abduct the arm, with the middle deltoid generating the most abduction force. The anterior fibers are active during forward elevation and adduction of the glenohumeral joint, whereas the posterior fibers function to extend the shoulder and externally rotate the humerus. Trigger points (TrPs) in the deltoid muscle do not refer pain to distant areas; the pain is localized and rarely refers past the elbow. A patient with deltoid TrPs typically reports having shoulder pain, particularly with an active movement of the glenohumeral joint. Pain may be felt deeply when moving the humerus into horizontal adduction across the front of the chest and rotating the humerus internally and externally during functional activities. Activating and perpetuating factors for TrPs in this muscle include impact trauma from contact sports or getting hit by a ball, sudden overload to the muscles in an effort to break a fall, poor workstation setup, and repetitive activities. Deltoid TrPs are commonly misdiagnosed as rotator cuff (RTC) tears, bicipital tendinitis, subdeltoid bursitis, glenohumeral joint arthritis, subacromial pain (impingement) syndrome, or C5 radicular pain. Corrective actions for this muscle include addressing ergonomic setup, wearing protective padding during contact sports, ensuring proper arm support during exercise, and performing self-pressure release of TrPs.

2. ANATOMIC CONSIDERATIONS

The deltoid muscle is a large muscle that forms the rounded shape of the shoulder.¹ It is divided into three parts: the anterior, the middle, and the posterior fibers. The directions of the anterior and the posterior fibers are essentially parallel to each other, covering the anterior and the posterior aspects of the shoulder. The anterior and the posterior fibers exhibit a fusiform arrangement of long fiber bundles that extend directly from the origin to the insertion. The middle deltoid fibers are multipennate in their structure. The muscle fibers of the entire muscle converge distally near the midpoint of the lateral aspect of the shaft of the humerus and attach to the deltoid tubercle near the brachialis origin.² The muscle also gives off an expansion into the deep brachial fascia that may reach the forearm and allows for reciprocal feedback between the muscles and fascia of the upper arm and the forearm during functional activities.³

Anterior Deltoid Fibers

The anterior fibers of the deltoid muscle originate from the anterior border and the superior surface of the lateral one-third of the clavicle and travel posterolaterally to insert midshaft on the lateral aspect of the humerus at the deltoid tubercle (Figure 28-1). The distal tendon is thick and fibrous and joins the middle and posterior deltoid fibers to form a central tendon at the insertion on the lateral tubercle.²

Figure 28-1. Attachments of the right deltoid muscle (dark red). Compare the diagonal and complexly interwoven fibers of the middle fibers with the simple fusiform arrangement in the anterior and posterior fibers. The schematic of Figure 28-3 shows how, in principle, these fiber arrangements affect endplate distribution.

Middle Deltoid Fibers

The middle fibers originate from the lateral margin and the superior surface of the

acromion and travel inferiorly to join the anterior and posterior deltoid muscle bellies to insert midshaft on the lateral tubercle of the humerus. The middle deltoid fibers are multipennate and slant obliquely between proximal tendons (usually four) that extend downward from the acromion into the substance of the muscle. Three interdigitating tendons extend upward from the lateral tubercle and are connected by short muscle fibers that generate powerful traction.²

Posterior Deltoid Fibers

The posterior fibers originate on the lower edge of the crest of the spine of the scapula and travel anterolaterally and join the middle and anterior fibers to insert midshaft on the lateral tubercle of the humerus. Its fiber direction is essentially parallel to the anterior fibers.²

2.1. Innervation and Vascularization

The deltoid muscle is innervated by the anterior rami of the C5 and C6 spinal roots via a branch of the posterior cord known as the axillary nerve. The axillary nerve divides into anterior and posterior branches just distal to the subscapularis muscle. The anterior branch innervates the anterior and middle deltoid muscles and the posterior branch innervates the posterior deltoid and teres minor muscles.⁴ Loukas et al⁵ analyzed 100 nerve specimens from 50 cadavers and in 18% of the cases, the anterior branch of the axillary nerve provided a branch to the posterior part of the deltoid muscle, and in 38% of specimens the middle part of the deltoid muscle received dual innervation from both the anterior and posterior parts of the axillary nerve.

The deltoid muscle receives its vascularization via the deltoid branches of the thoracoacromial, and acromial arteries, and the anterior and posterior circumflex humeral arteries. The deltoid branches of the thoracoacromial and acromial arteries supply the anterior deltoid muscle and the posterior circumflex humeral artery supplies the middle and posterior fibers of the muscle. The anterior circumflex humeral artery also supplies the anterior fibers of the deltoid muscle.²

2.2. Function

The anterior, middle, and posterior deltoid muscles can act separately or in conjunction with one another to generate motion at the glenohumeral joint. The efficiency of the deltoid muscle is dependent on the health of the RTC muscles because movements of the shoulder girdle are complex and require coordinated muscle activation patterns.⁶ A simultaneous contraction of the anterior, middle, and posterior fibers of the deltoid muscle contribute to shoulder elevation.²

Earlier it was thought that the deltoid and the supraspinatus muscles had different activation patterns during shoulder abduction. However, the electrical activity of both the deltoid and supraspinatus muscles increases progressively throughout abduction. With elevation in the plane of the scapula, the supraspinatus muscle activity is higher in the first

arc of motion and the anterior and middle deltoid muscle bellies have higher activity in the second and third arcs of motion. This is primarily due to the differing lengths of the lever arms of each muscle as they move through the shoulder elevation motion. Electromyography (EMG) activity was found to be greatest in the middle deltoid and supraspinatus muscles in the 30° to 60° range of scapular elevation.⁷ Witte et al⁸ found a significant increase in deltoid muscle activation (all three portions) in response to glenohumeral elevation moments. The supraspinatus muscle response to increasing glenohumeral moments was highly variable without a consistent increase in activity. They conclude that the deltoid and supraspinatus muscles may contribute to glenohumeral moments in a complimentary manner.

Other authors have also found utilizing surface and fine wire EMG that the deltoid (all portions), supraspinatus, infraspinatus, upper trapezius, lower trapezius, and serratus anterior muscles all activate prior to the onset of the humerus motion during coronal plane abduction, elevation in the plane of the scapula, and elevation in the sagittal plane.^{6,9} This activation pattern was observed regardless of the external load of the arm.⁶ Peak activity of the middle deltoid fibers was observed at 100° abduction, anterior deltoid fibers at 125°, and posterior deltoid fibers at 140°.⁹

Anterior Deltoid Fibers

During shoulder flexion, the anterior deltoid fibers, supraspinatus, infraspinatus, pectoralis major, serratus anterior, upper and lower trapezius muscles activate moderately prior to limb movement and increase proportionally with a 20% and 60% load of the subject's repetition maximum.¹⁰ In an older study, the anterior deltoid fibers were recruited most strongly when flexion and adduction movements were combined to move the arm obliquely upward inclining toward midline.¹¹ The attachments of the anterior deltoid fibers appear as though they should internally rotate the arm, but the use of this action is questioned by electromyographers and the deltoid muscle appears to contribute little to internal or external rotation.¹² However, when the humerus is rotated internally to 45° during an elevation task, the anterior deltoid muscle is maximally activated. In fact, during pushing the anterior deltoid muscle is maximally active.¹³

Middle Deltoid Fibers

The middle fibers of the deltoid muscle are designed structurally for abduction, during which they show strong EMG response. The linear increase in EMG activity during abduction of the arm indicates a primary abduction function of the middle part of these fibers with a peak activity at 110° abduction.⁹ With increasing loads, the middle deltoid muscle activation pattern increased similarly to the supraspinatus muscle pattern, systematically supporting the "law of proportional activation."¹⁴ The activation pattern of abduction in the plane of the scapula is established with low loads and is maintained as the load is increased in subjects with no history of neck or shoulder dysfunction.¹⁴ However,

during flexion, a nonlinear increase in the activity of the middle fibers between 60° and 90° of arm elevation indicates that its flexor action is enhanced as arm elevation increases,¹⁵ and an overall increase in maximal voluntary contraction was noted with an external load in the upper extremity.¹⁰ Gregory et al¹⁶ investigated the role of the middle deltoid fibers in the elevation and coaptation of the glenohumeral joint in five healthy subjects and 10 with full-thickness RTC tears. They found that the anterior fibers of the middle deltoid muscle have an increased coaptation role in elevation and may improve shoulder function in the presence of an RTC tear. They conclude that a stronger efficient anterior portion of the middle deltoid muscle may assist a weakened RTC during elevation due to its coaptation forces.¹⁶ During pushing, the middle deltoid fibers were found to be moderately active along with the pectoralis major, infraspinatus, biceps brachii, and triceps brachii muscles.¹³

Posterior Deltoid Fibers

The posterior fibers of the deltoid muscle extend the arm with the latissimus dorsi and teres major muscles. This function is essential to reach behind the body for dressing and toileting activities. Anatomically, the posterior fibers should assist the external rotation of the shoulder,² but that function has not been substantiated electromyographically. It is now thought that these fibers do not lend a significant clinical contribution to the rotational movement of the shoulder.¹⁷ The moment arms of the middle and posterior deltoid muscles also increased with rotation, but the changes were not considered clinically relevant.¹⁷ In addition to shoulder extension, the posterior deltoid fibers act during abduction in the coronal plane and elevation in the plane of scapula and in the forward elevation of the shoulder. However, Wickham et al⁹ found that the peak activity of the posterior deltoid fibers was at 140° of abduction in the coronal plane and this activity was thought to counterbalance the abduction moment. The posterior deltoid muscle was found to be maximally active during pulling activity and during quick throwing activities.¹³

Driving a car with the hands on top of the steering wheel chiefly activated the anterior, and to a lesser extent the middle, part(s) of the muscle.¹⁸ When the steering wheel is held in the center position, there is a co-contraction of shoulder muscles to stabilize the wheel. During steering maneuvers, the posterior deltoid fibers provide the greatest contribution as steering torque increases.¹⁸

During freestyle swimming, of which the crawl stroke has been studied the most,^{19–21} an EMG analysis of 12 muscles found the anterior and middle deltoid fibers had an 80% maximal voluntary contraction during early to late recovery phases. In a study that looked at EMG activity in swimmers with painful shoulders, the normally marked increase in the middle deltoid fiber activity during the beginning and the end recovery phases was significantly inhibited. In the anterior deltoid muscle, the marked activity of the early recovery and the late recovery phases was significantly inhibited. Unfortunately, the structures responsible for the pain were not identified in this study.¹⁹ Trigger points can cause this kind of a muscle inhibition when a person performs a well-learned and repetitive activity.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 28-1 grossly represents the functional unit of the deltoid muscle.²²

Box 28-1 Functional unit of the deltoid muscle

Action	Synergists	Antagonist
Shoulder abduction	Supraspinatus	Teres major Latissimus dorsi Pectoralis major
Shoulder flexion	Coracobrachialis Pectoralis major Biceps brachii long head	Triceps brachii long head Teres major Latissimus dorsi
Shoulder extension	Triceps brachii long head Teres major Latissimus dorsi	Coracobrachialis Pectoralis major Biceps brachii long head

The supraspinatus, infraspinatus, subscapularis, upper trapezius, lower trapezius, and serratus anterior muscles act synergistically during abduction in the coronal plane (shoulder abduction), elevation in the plane of the scapula, and elevation in the sagittal plane (shoulder flexion).

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the anterior deltoid fibers (Figure 28-2A) refer pain to the anterior and middle areas of the shoulder^{23, 24} and the anterolateral aspect of the upper arm. Trigger points in the posterior deltoid muscle (Figure 28-2B) refer pain that concentrates over the posterior shoulder area, sometimes referring into the adjacent posterior aspect of the upper extremity. Trigger points in the middle deltoid muscle produce pain centered in that region of the shoulder with some referred pain to adjacent areas (Figure 28-2C). Typically, pain is deeply localized to the shoulder and rarely refers past the elbow. The deltoid muscle lacks any distant projection of referred pain. Referred pain from this muscle was demonstrated

experimentally by the injection of hypertonic saline.²⁵

Figure 28-2. Referred pain patterns (dark red) from TrPs in the right deltoid muscle (light red). A, Pain pattern from TrPs in the anterior fibers of the muscle. B, Pain pattern from the posterior fibers. C, Pain pattern from TrPs in the middle fibers of the muscle. The distribution of TrPs in the anterior and posterior parts of the deltoid muscle has a different pattern from the distribution of TrPs in the middle deltoid muscle. Figure 28-3 provides a possible explanation for this clinical phenomenon. D, Right deltoid muscle.

3.2. Symptoms

Trigger points in the anterior deltoid muscle cause pain in the front of the shoulder and may refer into the front of the upper arm. In contrast, TrPs in the posterior deltoid muscle

cause pain in the back of the shoulder with referral occasionally into the back and side of the upper arm and less frequently in the front of the shoulder joint. Trigger points in the middle deltoid muscle most often cause pain only in the lateral aspect of the shoulder over the muscle belly, without referral into the upper arm. Clinical experience suggests that TrPs in the deltoid muscle are usually related to inhibition of the supraspinatus muscle caused by TrPs in that muscle.

Often, a patient with deltoid TrPs presents with symptoms that began after a traumatic impact to the shoulder during contact sports or other activities. Trigger points in the deltoid muscle can also be activated during repetitive strain injuries on work activities. In fact, Fernández de las Peñas et al²⁶ observed that manual and office workers had a similar number of TrPs in the shoulder muscles. Patients with TrPs in the deltoid muscle complain of pain that is deep in the shoulder area with active shoulder motion and, less frequently, of pain at rest (Figure 28-2). The patient with anterior deltoid TrPs has difficulty raising the upper extremity to the shoulder level and reaching behind the body at the shoulder level. A patient with multiple deltoid TrPs may present with impairment of strength or a total inability to raise the upper extremity to the shoulder level due to painful weakness. Hains et al²⁷ found that the application of ischemic compression on TrPs in the shoulder muscles, including the deltoid muscle, was effective for reducing the symptoms of patients experiencing chronic shoulder pain.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For effective examination of the deltoid muscle, the clinician should assess the shoulder girdle posture, active and passive ranges of motion of the shoulder, and scapulohumeral rhythm, paying close attention to muscle activation patterns. To identify TrPs in the deltoid muscle that may be limiting the range of motion and thus influencing dysfunction, the clinician should identify the limited range of motion by performing specific excitability testing for all parts of the deltoid muscle.

Examination of muscle activation patterns is particularly important for individuals with TrPs of shoulder muscles because TrPs have been found to induce delayed and inconsistent activation of the upper trapezius and serratus anterior muscles during arm elevation.^{28, 29} Also, TrPs in the posterior deltoid fibers are able to reduce the efficiency of reciprocal inhibition of the anterior deltoid fibers during arm elevation.³⁰ In the light of the above findings and those of Bron et al,³¹ 38% of patients with non-specific shoulder pain exhibited TrPs in the anterior fibers of the deltoid muscle, and a thorough examination of the deltoid muscle in any patient presenting with shoulder pain is very important.

Accessory joint motion of the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic joints should be manually tested. Often, restrictions in the sternoclavicular joint can cause impairment in shoulder elevation, contributing to alterations in muscle

activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns contributing to the overload of the deltoid muscle by inhibiting supraspinatus muscle function. Muscle-specific resisted testing should be carried out to identify impairments in muscle function and reproduction of painful symptoms.

Involvement of the anterior deltoid fibers impairs the performance of the Apley's extension, internal rotation, and adduction test (Figure 21-3A); whereas TrPs in the posterior deltoid fibers bar the execution of the Apley scratch test (flexion, abduction and external rotation) (Figure 21-3B): the arm can reach over the head but not behind it, secondary to pain induced by a forceful contraction of the affected posterior deltoid fibers in the shortened position.

3.4. Trigger Point Examination

The deltoid muscle's superficial location makes it easy to palpate the muscle bellies utilizing cross-fiber flat palpation to identify a taut band and TrP. Examination is best performed with the arm slightly abducted (to $\sim 30^\circ$) to relax the muscle. Bron et al³¹ reported moderate reliability for palpation of TrPs in the anterior and middle fibers of the deltoid muscle. The most reliable characteristics identified by the study of Bron et al³² were a palpable taut band, a jump sign, and the presence of referred pain.

The location of endplates in the deltoid muscle is illustrated schematically in Figure 28-3 and reflects the difference in endplate distribution within each part of the muscle. An endplate is normally located close to the mid-portion of the muscle fiber that it supplies. The endplate zone in a fusiform muscle, like the anterior and posterior deltoid fibers, is a single, sometimes irregular, band of motor endplates extending across the mid-portion of the muscle. However, the endplates in the angulated fibers of the middle deltoid are widely distributed throughout the muscle.³³ Therefore, TrPs in the deltoid muscle can be located in any fibers of the muscle. Clinicians should carefully explore all the fibers to determine the most affected portion.

Figure 28-3. Schematic of the fiber arrangements and the corresponding distribution of the endplates (red dots) in the three parts of the deltoid muscle. An endplate is normally

located close to the middle of the muscle fiber that it innervates. The anterior and posterior parts of the muscle have a fusiform arrangement and their fibers are nearly parallel to the long axis of the muscle, an arrangement that provides speed at the expense of strength and results in a band of endplates across the middle of the muscle. The schematic for the middle part of the deltoid muscle shows a multipennate fiber arrangement that provides strength at the expense of speed. Schematic adapted with permission from Anderson JE. *Grant's Atlas of Anatomy*. 7th ed. Baltimore, MD: Williams & Wilkins; 1978.

Trigger points are common in patients complaining of shoulder pain. In a study of 72 subjects with chronic shoulder pain, 50% of patients had active TrPs in the middle deltoid fibers, 47% in the anterior deltoid muscle and 44% in the posterior deltoid fibers. The anterior fibers of the deltoid muscle also had a significant number of latent TrPs with 27% of the subjects affected.³¹ Deltoid TrPs have also been associated with whiplash-associated disorders³⁴ and work-related shoulder and neck complaints.²⁶ Trigger point involvement exclusive to the deltoid muscle is rare. During the examination, muscles that typically have associated TrPs should be evaluated and treated for full resolution of shoulder pain complaints.

Anterior Deltoid Fibers

Cross-fiber flat palpation of the muscle fibers is utilized to identify the taut bands associated with anterior deltoid TrPs (Figure 28-4A). Trigger points in this portion of the muscle are readily identifiable.

Figure 28-4. Cross-fiber flat palpation to identify trigger points in the (A) anterior, (B) middle, and (C) posterior fibers of the deltoid muscle.

Middle Deltoid Fibers

Trigger points in the middle fibers of the deltoid muscle may develop almost anywhere along the length of the muscle belly because this middle part of the muscle is multipennate and its motor endplates are widely distributed. Tenderness from enthesopathy of the supraspinatus attachment at the superior facet of the greater tuberosity of the humerus can be confused with tenderness associated with deltoid muscle TrPs. To differentiate tenderness from supraspinatus enthesopathy and that of a deltoid TrP, the arm is passively abducted to 90°, which protects the supraspinatus muscle attachment from digital pressure beneath the acromion while the deltoid TrPs remain tender to palpation (Figure 28-4B).

Posterior Deltoid Fibers

Posterior deltoid TrPs are typically located along the posterior margin of the muscle, slightly more distal than those of the anterior fibers. Cross-fiber flat palpation along the muscle belly should be utilized to identify TrPs in this portion of the muscle (Figure 28-4C).

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the deltoid muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³⁵ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. Trauma is a common cause of TrP formation in the deltoid muscle. The deltoid muscle is often overloaded in athletic activities such as swimming, overhead throwing, tennis, weight lifting, and skiing. Many of these activities require forceful flexion that can overload the deltoid muscle. Impact trauma may occur from a hit by a tennis or golf ball, from falling directly on the muscle, or from collisions during contact sports. The repeated recoil of a gun when shooting can also cause traumatization of the anterior deltoid muscle. Trauma by sudden overload can occur during a loss of balance when going down steps and reaching out to a bannister or railing to “catch a fall” causing a sudden overexertion and overstretch trauma to the deltoid muscle. Whiplash-associated disorders can be exacerbated by TrPs that form in the shoulder and cervical muscles as a result of trauma from a motor vehicle accident and are often the cause of the intractable neck and shoulder pain or headaches suffered by these patients.³⁴ Carrying heavy objects or lifting and holding children may also overload the deltoid and RTC muscles.

Trigger point formation in the anterior deltoid muscle can be caused by overload activation of the muscle, such as holding a power tool at the shoulder height or working at an improperly adjusted workspace. Improper ergonomics of an office workstation can cause increased and sustained activity in the deltoid muscle. Conte et al³⁶ investigated muscle co-contractions in the trunk and upper arm muscles utilizing superficial EMG during

controlled use of a computer touch pad and a traditional mouse control. These authors found that even though the use of the mouse required shoulder abduction, the use of the touchpad required a greater degree of movement accuracy and therefore more stabilization of the shoulder. They conclude that the use of a mouse with a laptop may reduce biomechanical risks for injury of shoulder and upper arm injuries.³⁶

Repetitive activities that require work with the arms elevated to shoulder or eye height for hours at a time may activate TrPs and can perpetuate them if the task is continued without alteration. Workers with chronic arm, neck, and shoulder pain often have TrPs in the shoulder and the cervical musculature including the deltoid muscle.²⁶ As expected, sustained computer work and poor posture may predispose subjects to increased TrP prevalence. Also, the prevalence of TrPs is similar between desk and manual workers, suggesting that they overuse the same muscles even though their work activities may be very different.²⁶

Repetitive overuse is also seen in competitive overhead athletes. The overhead volleyball or tennis serve can cause repetitive strain and TrP formation in the deltoid muscle. Osborne and Gatt³⁷ identified TrPs in volleyball players that developed after several long days of training and tournament play. Release of the TrPs restored an active range of motion and allowed the athletes to quickly return to competitive play. Episodic overexertion, such as unaccustomed deep-sea fishing, can also lead to TrP formation in the anterior deltoid fibers.

The posterior fibers of the deltoid muscle rarely develop TrPs as the result of activity in isolation. Typically, TrP formation occurs in association with TrPs in other muscles of the kinetic chain. However, specific overexercise may activate TrPs in the posterior deltoid muscle and may occur from activities such as excessive poling when skiing, or other repetitive exercises that require a pulling action.¹³

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.³⁷ Therefore, musculature in the referred pain areas for each muscle should also be considered. Often, release of the TrP in the associated muscle allows for an immediate decrease in the pressure pain threshold of the associated TrPs in the deltoid muscle.³⁸ This relationship is most common with TrPs in the infraspinatus muscle causing associated TrPs in the anterior deltoid muscle. Trigger points in the anterior part of the deltoid muscle are often associated with TrPs in the clavicular section of the pectoralis major muscle, the pectoralis minor muscle, the biceps brachii muscle, and in the posterior fibers of the deltoid muscle.

When a TrP is identified in posterior deltoid fibers, one should also examine the proximal third of the long head of the triceps brachii, the latissimus dorsi, and the teres major muscles for associated TrPs. The teres minor fibers are only aligned with the posterior deltoid muscle when the arm is held in full abduction; therefore, it is less likely to develop associated TrPs. Isolated TrPs in the posterior deltoid fibers rarely occur unless TrPs become activated by local injection of an irritant solution into the muscle. In these

instances, the TrP activity tends to be self-sustaining.

Because the deltoid muscle lies in the referred pain areas of both the infraspinatus and supraspinatus muscles, it rarely escapes the development of associated TrPs when these muscles have TrPs. Hong³⁹ reported that TrPs in the scalene or supraspinatus muscles can induce associated TrPs in the deltoid muscle. Pressure was applied to a TrP in the infraspinatus muscle, which caused referred pain over the front area of the shoulder. The pressure caused increased motor unit activity, or referred spasm, in the anterior deltoid muscle while recording needles in the biceps and triceps brachii muscles showed electrical silence.³⁸ Release of the TrP in the infraspinatus muscle caused a decrease in the pain pressure threshold of the TrP in the anterior deltoid muscle, despite the fact that no treatment was performed on the deltoid muscle.

If inactivation of deltoid TrPs restores only about 90° of abduction, then any active supraspinatus TrPs should be located and eliminated. This intervention usually restores the full range of arm motion in the overhead position, unless antagonists to shoulder abduction are also involved. Trigger points in the antagonists can negatively affect shoulder elevation. When TrPs are present in the posterior deltoid muscle, there is decreased reciprocal inhibition of the muscle during shoulder elevation.³⁰ This relationship can cause reduced efficiency of movement, which may lead to decreased muscle relaxation, disordered muscle activation patterns, and a sustained muscle overload to the anterior deltoid muscle. These are all precursors to TrP formation in the muscle agonist.

4.3. Associated Pathology

Deltoid TrPs are commonly misdiagnosed as RTC tears, bicipital tendinitis, subdeltoid bursitis, glenohumeral joint arthritis, impingement syndrome, or C5 radiculopathy. These conditions need to be considered in the differential diagnosis of shoulder pain symptoms. They may cause deep shoulder pain and tenderness and referred pain similar to that from deltoid TrPs, but they lack the specific physical signs of palpable bands, spot tenderness, and local twitch responses in the muscle. One of these conditions often coexist with deltoid TrPs, and in these cases, both conditions should be treated.

Referred pain from any part of the deltoid muscle can mimic pain arising from the glenohumeral joint⁴⁰ and thus, can easily be misdiagnosed as arthritis of that joint. Any TrP in the deltoid muscle should be inactivated and the therapeutic response observed before deciding to inject the shoulder joint. Sometimes both the muscle and the joint have to be treated.

When attention is directed only to the subacromial area of referred pain and tenderness, and TrPs in any or all three parts of the deltoid muscle are overlooked, a diagnosis of “subdeltoid bursitis” is often rendered. A normal bursa may then be injected, to the neglect of the active deltoid TrPs, often resulting in a poor therapeutic result.

The acromioclavicular joint underlies the proximal attachment of the anterior deltoid muscle. Pain due to sprain, subluxation, or complete dislocation or separation of this joint mimics the pain pattern of anterior deltoid TrPs, or vice versa. A sprain of the

acromioclavicular joint produces localized tenderness over the joint, rather than TrP tenderness in the deltoid muscle, and causes pain on passive mobilization of the joint and by arm motion that rotates or elevates the scapula. Acromioclavicular subluxation and dislocation are more likely during sports activities and following an automobile accident in which the patient was holding on to the steering wheel or stretched the arm out for protection. Passive horizontal abduction is painful at the acromioclavicular joint if it is involved.

Adhesive capsulitis, or frozen shoulder, is a condition of unknown etiology that will limit the available range of motion at the glenohumeral joint and is associated with considerable pain during active and passive movements of the shoulder. Often, these patients have TrPs present in the scapulothoracic and glenohumeral muscles, particularly the subscapularis muscle, which can contribute to the patient's pain and cause limited motion. Clewley et al⁴¹ treated a patient with adhesive capsulitis using TrP release. When an initial bout of cervicothoracic and thoracic thrust manipulation of the spine was ineffective, the surrounding shoulder musculature was evaluated for TrPs. They found TrPs present in the upper trapezius, levator scapula, deltoid, and infraspinatus muscles. Often the subscapularis muscle is also involved. Trigger point release by dry needling reduced the patient's pain significantly after two visits, which allowed for improved shoulder motion during functional activities and the introduction of higher grades of manual intervention for further progression of motion.⁴¹ This case demonstrates that releasing the TrPs decreases the pain and may allow for improved motion so that further manual treatment options may be tolerable for the patient.

5. CORRECTIVE ACTIONS

Chronic shoulder pain in desk workers has been associated with both active and latent TrPs in the shoulder muscles including the deltoid muscle.^{26,31} As stated earlier, a poor ergonomic setup can cause prolonged strain through the deltoid muscle, and this may be a main generator of neck and shoulder pain for employees who work long hours at a desk. Therefore, a thorough ergonomic assessment of the workspace and proper adjustment of the keyboard so that the elbow is supported at approximately 90° of flexion helps decrease the overload to the muscle and potentially eliminate pain. Several checklists can be found on the Internet regarding proper workstation arrangement and many companies have employees on staff who can provide an ergonomic assessment of a workspace. Physical or occupational therapists may be consulted to provide proper recommendations for adjustments to improve comfort.

In addition to postural adjustments, other mechanical stress factors also need to be corrected. Heavy lifting should be performed with the arm rotated such that the thumb is turned in the direction that unloads the affected part of the deltoid muscle. To effectively unload the anterior deltoid fibers, the arm should be rotated externally. Internal rotation thus unloads the posterior fibers.

The patient should take precautions on stairs and prevent potential deltoid muscle

overload that can result from being forced to quickly grab a hand railing. Traversing stairs slowly while holding onto railings, in addition to visually watching foot placement, may prevent a near fall and recurrence of muscle overload.

Athletes participating in contact sports should use protective padding over the anterior portion of the shoulder. Shooting enthusiasts should place a pad in front of the shoulder or use a garment specifically designed to minimize the direct trauma of gun recoil. This helps prevent further pain and irritation and helps prevent TrP formation.

Supporting the arm with a towel roll in the axilla during targeted exercises and placing the shoulder in 30° of abduction do not alter middle deltoid muscle activation but significantly increases posterior deltoid activation. In a side-lying position, using a towel roll in the axilla increases the maximal voluntary contraction of the posterior deltoid muscle, while significantly decreasing it in the middle deltoid muscle. Utilization of a towel roll in standing and side-lying should be considered for focused training of the posterior deltoid muscle or relaxation of the middle deltoid muscle.^{42,43} Investigators have demonstrated that prone horizontal abduction at 90° abduction with full external rotation⁴⁴ or 100° abduction with full external rotation⁴³ produces 80% to 88% maximal voluntary contraction of the middle and posterior deltoid portions, respectively. Although the deltoid muscle does not have a specific role in the rotation of the humerus, internal and external rotation exercises in standing can be used as a starting point for neuromuscular reeducation of this muscle.⁴²⁻⁴⁴

Trigger point pressure release applied with the deltoid muscle relaxed in a position of ease (supported at about 45° of abduction is optimal) can be particularly effective (Figure 28-5). Pressure should be uncomfortable but tolerable, and it can be effectively applied for bouts as short as 15 seconds in duration.²⁶ If the TrP is not readily accessible for digital compression, a tennis ball can be used against a wall to apply pressure over the TrP. Patients can also use commercially available tools to assist with pressure application.

Figure 28-5. Self-pressure release of TrPs of anterior fibers of the deltoid.

Clinicians can teach the patient self-pressure release of TrPs in the deltoid muscle. Daily gentle passive stretching of the affected part of the muscle may also be performed for pain relief and to maintain gains achieved after TrP release (Figure 28-6A and B). These stretches can be performed under a warm shower with water directed over the muscle for increased comfort during stretching.

Coracobrachialis Muscle

“Shadowy Scandalmonger”

Joseph M. Donnelly and Leigh E. Palubinskas

1. INTRODUCTION

The coracobrachialis muscle is a small muscle located in the anterior compartment of the shoulder that is frequently overlooked as a source of shoulder pain. The muscle attaches to the apex of the coracoid process, and distally it inserts onto the medial border of the humerus midway along the humeral shaft between the attachments of the triceps brachii and brachialis muscles. It is innervated by the musculocutaneous nerve. The main function of the coracobrachialis muscle is to assist with flexion and adduction of the shoulder. When the coracobrachialis muscle acts in conjunction with the synergistic muscles of its functional unit, it also provides inferior and anterior stability to the glenohumeral joint when the arm is abducted. Trigger points (TrPs) in the coracobrachialis muscle typically cause deep pain in the anterior aspect of the shoulder that may also refer into the posterior aspect of the upper arm and forearm as well as the dorsum of the hand. The pain referral pattern may also extend into the third digit of the hand in extreme cases. The patient may have symptoms when reaching behind the back (as in retrieving a wallet or tucking in a shirt) when the arm is elevated with the elbow bent and when reaching across the middle of the body (as in attempting to fasten a seat belt). Activation and perpetuation of TrPs in the coracobrachialis muscle usually result from acute repetitive overload with activities such as lifting heavy objects with the arms outstretched, push-ups or heavy bench pressing, and throwing. Differential diagnosis should include an assessment for C7 radicular pain or radiculopathy, carpal tunnel syndrome, subacromial bursitis, supraspinatus tendinitis, and acromioclavicular joint dysfunction. Corrective actions include effective posture during prolonged activities, self-pressure release of TrPs, self-stretching exercises, and avoidance of repetitive or heavy lifting with the arms outstretched or overhead. Clinically, TrPs in the coracobrachialis muscle most often occur secondary to TrPs in the other muscles of its functional unit.

2. ANATOMIC CONSIDERATIONS

The coracobrachialis muscle attaches proximally to the apex of the coracoid process, deep to the tendon of the short head of the biceps brachii muscle and with fibers connecting to the proximal aspect of the short head of the biceps brachii tendon (Figure 29-1). Distally, it attaches to the medial border of the humerus midway along the humeral shaft between the attachments of the triceps brachii and the brachialis muscles.¹ The coracobrachialis muscle lies over the subscapularis muscle and is separated from it by the coracobrachialis bursa.²

Figure 29-1. Usual attachments of the coracobrachialis muscle (red): proximally to the tip of the coracoid process, and distally to a line along the humerus extending almost to midshaft. The short head of the biceps brachii muscle (which has been cut and turned up) has a

shared origin with the coracobrachialis muscle at the coracoid process.

Anatomic variations of the coracobrachialis muscle include the extension of its humeral attachment to the medial epicondyle and the total absence of the muscle.³ Additional accessory slips of the muscle have also been found and may be attached to the lesser tubercle,¹ medial epicondyle,^{4,5} triceps brachii muscle,⁶ or the medial intermuscular septum.⁷

2.1. Innervation and Vascularization

The brachial neurovascular bundle (comprised of the median nerve, the musculocutaneous nerve, the ulnar nerve, and the brachial artery) passes deep to the tendinous attachment of the pectoralis minor muscle at the coracoid process and courses down the arm dorsally and medially to the coracobrachialis muscle. When palpating this muscle or treating TrPs in this region, it is important to be mindful of the location of this bundle to avoid damage. These nerves can be easily and painfully damaged by forceful compression against the humerus.

The coracobrachialis muscle is innervated by the musculocutaneous nerve, which arises from the lateral cord of the brachial plexus and is derived from the cervical ventral rami at levels C5, C6, and C7.¹ Most references describe the coracobrachialis muscle as being innervated by the C5, C6, and C7 spinal nerves. However, the spinal nerve composition of the nerve branches innervating the coracobrachialis muscle can contain only fibers from C6 and C7.^{8,9} This description is contrary to the generally accepted innervation levels for this muscle but has been validated in more than one study.

Once the musculocutaneous branch separates from the nerve trunk, it pierces the coracobrachialis muscle in the mid-portion of the muscle belly beneath the pectoralis major muscle, dividing the muscle into clearly defined superficial and deep portions.^{3,10} The nerve then descends between the biceps brachii and brachialis muscles to the lateral side of the arm.¹ Anatomic studies have found instances where the musculocutaneous nerve does not pierce the coracobrachialis muscle, but traverses the length of the muscle.¹¹⁻¹⁵ This finding can have implications for surgical procedures,¹⁵ nerve blocks,¹² and needle insertion into the muscle or anterior shoulder compartment.

The vascular supply to the deep portion of the coracobrachialis muscle arises from the branches of the axillary artery and anterior humeral circumflex artery. Branches from the thoracoacromial artery supply the superficial portion of the muscle.¹

2.2. Function

The coracobrachialis muscle assists with flexion and adduction of the arm at the glenohumeral joint.^{1,3,16-18} The coracobrachialis muscle may be a strong contributor to glenohumeral adduction based on its angle of insertion. It also acts in conjunction with the anterior fibers of the deltoid muscle to resist deviation from the coronal plane of motion

when the arm is abducted.¹

When the coracobrachialis muscle acts in conjunction with the short head of the biceps brachii muscle, it assists to stabilize the glenohumeral joint. When contracted by faradic stimulation while the arm is held in the abducted position, the coracobrachialis muscle forcefully draws the humerus toward the glenoid cavity.¹⁹ Halder et al found that the coracobrachialis muscle also provides considerable superior translating, in effect helping stabilize the glenohumeral joint in the inferior direction when the arm is moved into abduction.²⁰ When the shoulder is moved into extension, the coracobrachialis muscle provides an anterior stabilizing force to the humeral head. This function is most prevalent when confirmed anterior shoulder instability is present, and therefore, the coracobrachialis muscle provides positional dynamic stability as it wraps across the anterior humeral head just over the subscapularis muscle.

The muscle's insertion on the medial shaft of the humerus allows it to be elongated by both internal and external rotation of the shoulder. It has been reported that the muscle assists in returning the arm to neutral from these positions.^{3,18}

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 29-1 grossly represents the functional unit of the coracobrachialis muscle.²¹

Box 29-1 Functional unit of the coracobrachialis muscle

Action	Synergists	Antagonist
Shoulder flexion	Deltoid (anterior fibers) Biceps brachii short head Pectoralis major	Teres major Latissimus dorsi Triceps brachii long head Deltoid (posterior fibers)
Shoulder adduction	Teres major Latissimus dorsi Pectoralis major	Deltoid Supraspinatus

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Referred pain from TrPs in the coracobrachialis muscle is primarily located in the anterior aspect of the shoulder in the region of the anterior fibers of the deltoid muscle (Figure 29-2). Pain may also spread down the posterior aspect of the arm, concentrating over the triceps brachii muscle, the dorsum of the forearm, and the dorsum of the hand extending to the tip of the middle finger. Often, the elbow and wrist joints are not involved in the patient's report of symptoms.

Figure 29-2. Pain pattern (red) referred from a TrP in the right coracobrachialis muscle. Trigger points are likely to be found as far distally as the middle of the muscle belly. In patients with milder involvement, the pain may extend only to the elbow.

The more active the TrPs, the greater the extent of the referred pain, the more intense the pain, and the more likely the pain is to persist at rest. Also, the TrPs are tenderer, the taut bands are tenser, and the local twitch responses are more vigorous.

3.2. Symptoms

Trigger points in the coracobrachialis muscle should be considered when the patient reports having upper limb pain, particularly in the front of the shoulder or the back of the arm. Patients with TrPs in the coracobrachialis muscle may experience pain and difficulty when reaching behind the body and across the lower back. The patient may report pain when reaching into a back pocket or tucking in a shirt. When only the coracobrachialis muscle is involved, neither reaching the arm up nor reaching out to the side with the elbow bent (as in touching the top of the head) is painful. However, reaching up into full forward elevation and then moving the arm behind the ear toward the middle of the body causes pain because of the contraction of the coracobrachialis muscle in the shortened position.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. A comprehensive examination of the coracobrachialis muscle should include observation of shoulder girdle posture and scapular position as well as active and passive ranges of motion of the shoulder girdle, with special attention paid to muscle activation patterns and scapulohumeral rhythm. The clinician should note when and where pain occurs.

With coracobrachialis TrPs, the arm can be flexed as far as the ear but not behind it as this adds an aggravating adduction moment. Contracting the muscle in the shortened position causes pain.

Muscle-specific resisted testing should be performed to identify impairments in muscle function and reproduction of painful symptoms. To test the strength of the coracobrachialis muscle, the patient first elevates the arm to about 45° of flexion with external rotation. The patient's elbow should be flexed and the forearm fully supinated to minimize biceps brachii muscle's assistance.¹⁷ Inability to adequately resist pressure applied by the clinician can indicate inhibition caused by TrPs in the coracobrachialis muscle. If the coracobrachialis muscle has TrPs, resistance effort by the patient is likely to elicit pain.

The Apley's scratch test (extension, internal rotation, and adduction) (Figure 20-3A) reveals restriction in shoulder range of motion when there are TrPs in the involved coracobrachialis muscle. Reaching behind the body and across the lower back puts the muscle in a painful position due to the stretch of the coracobrachialis muscle that is caused by extreme internal rotation and extension. Typically, the patient has difficulty reaching past the midline of the back secondary to pain. Stretching the involved coracobrachialis muscle by passively extending the arm at the shoulder joint also causes pain particularly with the addition of an abduction component.²²

Accessory joint motion should be tested in the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic joints. Often, joint hypomobility in the sternoclavicular joint can cause impairment in shoulder elevation, which contributes to alterations in normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns, contributing to the overload of the coracobrachialis muscle.

Scapular position and humeral head position should be assessed at rest and during upper extremity elevation, as malalignment can be a significant contributing factor to coracobrachialis muscle overload during upper extremity functional activities that require combined flexion and adduction.

3.4. Trigger Point Examination

The patient should be positioned in a supine position with the arm abducted to 60° to allow access to the coracobrachialis muscle. Prior to palpation, the relation to other

structures should be considered. The coracobrachialis muscle crosses superficially to the attachments of the subscapularis, latissimus dorsi, and teres major muscles but lies deep to the pectoralis major and anterior deltoid muscles (Figure 29-3). Coracobrachialis TrPs are found by palpating the muscle against the humerus, sliding the finger into the axilla deep to the deltoid and pectoralis major muscles (Figure 29-4). The tip of the digit encounters the adjacent bellies of the short head of the biceps brachii muscle and, more posteriorly, the coracobrachialis muscle at a level where about half of the biceps brachii muscle fibers become attached to their common tendon. The axillary neurovascular bundle passes along the coracobrachialis muscle²³ and should be displaced posteriorly to permit the digit to explore the fibers of the coracobrachialis muscle for taut bands by strumming the muscle against the humerus. Trigger points are typically found approximately mid-muscle. The attachment area may also feel indurated and respond to digital pressure with referred pain.

Figure 29-3. Muscular regional anatomy of the right shoulder, seen from the front. The coracobrachialis muscle (dark red) crosses superficial to the attachments of the subscapularis, latissimus dorsi, and teres major muscles but lies deep to the pectoralis major and anterior deltoid muscles. For clarity, the serratus anterior muscle is not shown. The coracobrachialis muscle lies medial to the short head of the biceps brachii muscle and is palpated for TrPs against the humerus in the anterior axillary fossa, deep to the pectoralis major muscle.

Figure 29-4. Palpation of coracobrachialis muscle for TrPs.

Evaluation for Trigger Points

Evaluation for TrPs should include cross-fiber flat palpation of the whole muscle. Two areas of tenderness are common in this muscle, more proximally and more distally. Trigger point tenderness is typically located approximately mid-muscle but could be present anywhere throughout the muscle belly. Attachment tenderness may also be located in the region of the proximal musculotendinous junction, although it also can be distal and most likely represents enthesopathy secondary to sustained tension caused by taut bands of the TrPs.²⁴

Trigger points may be identified by passively moving the arm through a range that lengthens or stretches the coracobrachialis muscle. However, involvement of the coracobrachialis muscle is usually discovered when the patient returns following a successful inactivation of multiple TrPs in other shoulder muscles, especially the anterior deltoid and biceps brachii muscles. Although there is no recurrence of tenderness or taut bands in the muscles treated earlier, the patient reports posterior arm pain and deep tenderness that remains in the region of the anterior deltoid muscle. Careful examination reveals tenderness that lies deeper than that in the deltoid muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or an activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the coracobrachialis muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁵ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Because it is a strong shoulder adductor, coracobrachialis TrPs can be activated by activities involving repetitive upper limb exertion such as push-ups, rock climbing, swimming, throwing a ball, and playing tennis or golf. Occupations that require pulling objects downward, lowering objects from the shoulder height or above down to the floor, or lifting heavy objects with the arms extended may put a patient at risk to develop coracobrachialis TrPs. Prolonged immobilization of the shoulder joint in an adducted, internally rotated position from a surgical procedure, or self-immobilization due to pain, may also activate TrPs in the coracobrachialis muscle.

4.2. Associated Trigger Points

Associated TrPs can develop in muscles within the referred pain areas resultant from an active TrP. Therefore, muscles in the referred pain areas for each involved muscle should also be considered for examination.²⁶ Patients rarely present with symptoms of TrPs in this muscle alone. Coracobrachialis TrPs may generally develop in association with TrPs in functionally related muscles, such as the anterior or posterior deltoid portions, the biceps brachii (short head), the supraspinatus, and the triceps brachii (long head) muscles. Therefore, when evaluating a patient with pain in the anterior shoulder or posterior arm, it is necessary to evaluate muscles of the functional unit and treat TrPs in these muscles first. Often, coracobrachialis TrPs are identified after these associated TrPs have been treated and pain continues to persist.

4.3. Associated Pathology

Diagnoses that can present similarly to coracobrachialis TrPs includes C7 radicular pain (due to the area of pain reported by the patient), carpal tunnel syndrome, subacromial bursitis, subacromial pain syndrome (impingement), supraspinatus tendinopathy, and acromioclavicular joint dysfunction. Tenderness elicited slightly inferior to the acromioclavicular joint could implicate an enthesopathy of the coracobrachialis muscle. If tenderness to palpation is more distal, coracobrachialis TrPs in the muscle belly are more likely.

An important differential diagnostic procedure to distinguish acromioclavicular joint dysfunction from coracobrachialis TrPs is performed by passively placing the affected arm in full horizontal adduction to stress the acromioclavicular joint. Additional application of

resistance to horizontal abduction in this fully adducted position increases the sensitivity of the test.²⁷ Either or both of these maneuvers elicit pain if there is an acromioclavicular joint dysfunction and should not elicit pain with coracobrachialis TrPs in isolation.

Tears of this muscle are rare and typically occur in combination with other shoulder muscles,²⁸ though three cases of isolated tears of the coracobrachialis muscle have been reported.²⁹ All resulted from forceful extension of the arm with the humerus in external rotation and abduction.

Entrapment of the musculocutaneous nerve by the coracobrachialis muscle can lead to weakness and wasting of the brachialis and biceps brachii muscles. Entrapment of the musculocutaneous nerve can be distinguished from a C5 or C6 radiculopathy or from a lateral cord lesion of the brachial plexus by the sparing of the coracobrachialis muscle. Pec 'ina and Bojanic³⁰ reported the case of an oarsman who practiced 500 push-ups daily and who presented with reduced size and strength of the biceps brachii muscle, absent biceps brachii tendon reflex, reduced biceps brachii muscle tone, and diminished sensation of the lateral surface of the forearm. Electrodiagnostic testing showed prolonged distal latencies and decreased amplitude of evoked responses in the biceps brachii and brachialis muscles, indicating musculocutaneous nerve compression. Three months after stopping the daily push-ups, muscle mass, strength, and sensation in the forearm had returned. Electrodiagnostic studies showed improvement as well. Because the coracobrachialis muscle function was unimpaired, entrapment of the musculocutaneous nerve must have been distal to the motor branch to the coracobrachialis muscle.

Additional case reports³¹⁻³³ describe similar painless loss of musculocutaneous nerve function distal to the coracobrachialis muscle following heavy exercise (weight lifting and building a rock wall) with functional recovery within a few months after cessation of the strenuous activity. Exercise-induced hypertrophy of the coracobrachialis muscle that caused pressure compromise of the nerve as it penetrated the muscle was assumed to be responsible in these cases. No mention was made of examining the coracobrachialis muscle for TrPs. Latent TrPs that cause no clinical report of pain can be associated with well-developed taut bands that produce serious dysfunction and muscle inhibition.³⁴⁻³⁶

There have also been several cases of proximal musculocutaneous nerve injury in baseball and softball pitchers.³⁷⁻⁴⁰ In these cases, the patients presented with acute pain in the anterior shoulder and weakness in the forearm supinators and elbow flexors. Sensory changes were present in the volar forearm, but onset was variable and in one case it was absent.³⁸ EMG testing showed isolated musculocutaneous nerve injury with sparing of the coracobrachialis muscle. Treatment for these players involved rest, anti-inflammatory medication, and physical therapy. In all cases, each of the throwers were able to return to their previous level of play without any surgical intervention. It is unclear why these throwers developed this condition, but it is hypothesized that a combination of anatomic variance and exercise-specific training contributed to the cause.³⁷ In both softball and baseball pitching, the arm is placed in a position that applies significant traction along the course of the nerve that could cause damage.³⁹

5. CORRECTIVE ACTIONS

If coracobrachialis TrPs are suspected to be the cause of pain, repetitive or habitual movements that overuse the shoulder flexors such as repetitive or heavy lifting overhead, push-ups, bench press or inclined bench press, and repetitive throwing should be avoided. Lifting should be modified to keep elbows close to the body.

Sleeping positions can be particularly troublesome due to prolonged aggravating postures. The individual with coracobrachialis TrPs may be most comfortable sleeping on the back or on the pain-free side. When the patient lies on the uninvolved side, sleep comfort is improved by supporting the uppermost arm in a neutral position with the elbow and forearm placed on a pillow (Figure 22-4A) to avoid prolonged shortening of the affected coracobrachialis muscle. A pillow placed between the arm and the body can also be used to keep the arm in a neutral position when lying face up (Figure 22-4B). Another option is to place the pillow under the arm, perpendicular to the body, to keep the arm out of adduction and internal rotation and in a resting length–tension position for the coracobrachialis muscle. Patients should be cautioned regarding lying in bed with their arm(s) above their head in an abducted and externally rotated position, as this position keeps the coracobrachialis muscle in a shortened position and could cause increased pain from TrPs.

The patient may inactivate coracobrachialis TrPs with the application of self-release in the seated (Figure 29-5A), standing, or lying position (Figure 29-5B). Taking the hand of the unaffected side, the patient places the pad of the thumb along the humerus in the underarm beneath the pectoralis major muscle (Figure 29-5B). The thumb is pressed on the inner side of the bone in the underarm. The elbow is pressed into the side of the body to feel the coracobrachialis muscle contract. After finding the tender spot, a gentle pressure is applied for 30 seconds or until the pain decreases. This release may be repeated three to five times. Forceful pressure should be avoided as many nerves travel through this region. If any numbness or tingling occurs, the position of the thumb should be modified.

Figure 29-5. Self-pressure release of TrPs in the coracobrachialis muscle. A, Seated with towel roll to provide better access to the muscle. B, Lying down.

The patient should learn to release the TrP tightness by slowly and firmly stretching the coracobrachialis muscle by using the mid-arm position in a doorway to stretch into horizontal abduction with the humerus in internal rotation and the forearm in pronation (thumb and arm turned down) (Figure 29-6). The gentle stretch should be held for 30 seconds and repeated three to five times as needed, taking care not to overstretch. This sequence should be performed daily for optimal benefit.

Figure 29-6. Self-stretch in doorway with arm in mid-position.

Local application of moist heat to the muscle before or after the passive stretch exercise can reduce soreness. If soreness is a problem, an alternate-day program may be best and a post-stretching cold pack may help. Stretching too vigorously by using excessive body weight in the stretch should be avoided, and form may need to be checked by a professional to assist in modification for efficacy. Trigger points in this muscle rarely exist in isolation

and all other associated TrPs in the shoulder girdle should therefore be addressed to achieve full resolution of pain.

Biceps Brachii Muscle

“Upper Arm Agitator”

Joseph M. Donnelly and Leigh E. Palubinskas

1. INTRODUCTION

The powerful biceps brachii muscle spans the shoulder, elbow, and proximal radioulnar joints. It is a fusiform muscle with two distinct heads. Proximally, the long head of the biceps brachii muscle attaches to the superior margin of the glenoid cavity and glenoid labrum (biceps–labral complex), whereas the short head attaches with the coracobrachialis muscle to the coracoid process of the scapula. The two muscle heads fuse into a common tendon that attaches to the posterior aspect of the tuberosity of the radius. The muscle is innervated by the musculocutaneous nerve, which is comprised of spinal nerve root levels C5 and C6. The function of the biceps brachii muscle is complex because it spans three joints. Both heads of the muscle act synergistically to perform elbow flexion and supination of the forearm, and they both assist with flexion of the shoulder. The long head also assists with shoulder abduction when the arm is externally rotated and helps provide passive stability for the head of the humerus in the glenoid fossa. The short head assists with horizontal adduction of the shoulder. Pain referred from biceps brachii TrPs is typically located over the muscle and over the anterior region of the shoulder. Occasionally, pain is also referred to the suprascapular region and the antecubital space. Symptoms are most often exaggerated by repetitive flexion of the elbow or supination of the forearm. Patients may have difficulty reaching behind them with the elbow extended and the forearm supinated such as when pulling a rolling suitcase or when lifting items overhead with the arm outstretched and supinated. Examination of the patient should include testing to rule out bicipital tendinitis or biceps–labral complex dysfunction, subdeltoid bursitis, C5–C6 radicular pain, bicipital bursitis, and glenohumeral arthritis. The patient with TrPs in the biceps brachii muscle should avoid carrying or lifting items with the arm outstretched or supinated. Altering the sleeping posture to prevent prolonged flexion of the elbow can be helpful and self-stretch techniques can minimize pain associated with dysfunction of this muscle.

2. ANATOMIC CONSIDERATIONS

Long Head of Biceps Brachii

The biceps brachii muscle spans the shoulder, elbow, and proximal radioulnar joints (Figure 30-1). It is a fusiform muscle with two distinct proximal parts or “heads.”¹ The long head of the biceps brachii muscle originates from the supraglenoid tubercle at the superior margin of the glenoid cavity, the posterior–superior aspect of the glenoid labrum, and the glenoid rim of the scapula (Figure 30-1).^{1,2} This proximal region is commonly referred to as the biceps–labral complex.³ The tendon is enclosed in a synovial sheath within an opening of the glenohumeral joint capsule. This anatomic arrangement allows the long head tendon to be intracapsular but extrasynovial. The tendon travels distally over the humeral head and exits the joint capsule to reside within the bicipital (intertubercular) groove. The tendon of the long head is stabilized proximally within the glenohumeral joint capsule by the coracohumeral and superior glenohumeral ligaments, the supraspinatus tendon, and the superior portion of the subscapularis tendon. These structures are commonly referred to as the “biceps pulley” and are clearly visualized arthroscopically.⁴ On exiting the joint capsule into the bicipital groove, the tendon is supported by the transverse humeral ligament. The part of the tendon that resides in the main part of the bicipital groove is stabilized by a fascial expansion of the pectoralis major muscle (falciform ligament).² The falciform ligament attaches to both the medial and lateral lips of the bicipital groove and the glenohumeral joint capsule, adding stability to the tendon within the groove. The tendon is therefore stabilized by a variety of soft-tissue structures proximally. This orientation keeps the tendon stationary within the bicipital groove under a moving humerus during functional activities. The two heads of the biceps brachii muscle can be identified as individual heads from the glenohumeral joint distally approximately 7 to 10 cm proximal to the elbow joint.¹

Figure 30-1. Separate proximal attachments of the two heads of the biceps brachii muscle (red), which covers most of the brachialis muscle. The two heads of the biceps brachii muscle join distally to attach to the tuberosity of the radius. The forearm is fully supinated in this figure. The biceps brachii tendon wraps more than halfway around the radius in pronation. The brachialis muscle has been cut for clarity.

Short Head of Biceps Brachii

The short head originates from the coracoid process of the scapula by a thick, flat tendon with the coracobrachialis muscle. The tendon of the short head is lateral to the coracobrachialis muscle and anterior to the glenohumeral joint capsule. The short head travels inferolaterally, where it conjoins the long head of the biceps brachii muscle.

The common tendon of the two heads of the biceps brachii muscle attaches laterally to the posterior area of the tuberosity of the radius. The attachment faces the ulna when the forearm is supinated,¹ but in pronation the tendon wraps more than halfway around the radius.⁵ The distal tendon also fuses medially with the bicipital aponeurosis, which attaches to the deep fascia of the forearm flexors. The muscle also has fibrous attachments to the brachial and antebrachial fascia of the anterior arm and forearm, respectively.^{6,7}

The median and radial nerves lie along the medial and lateral borders of the distal portion of the biceps brachii and brachialis muscles. The endplates of a mature muscle form a somewhat ragged V-shaped band through the middle of the two heads.⁸ Postmortem examination of six biceps brachii muscles for innervation and corresponding distribution of motor endplates indicated that each head was divided into three distinct longitudinal compartments.⁹ The endplate zone of the long head is located slightly more proximal than that of the short head because of the difference in tendon arrangement and the innervation zone.¹⁰

Studies exploring the fiber composition of the biceps brachii muscle demonstrate an almost equal number of type-I (slow twitch) and type-II (fast twitch) fibers.^{11,12} This finding of two older studies suggests that the biceps brachii muscle acts both as a power muscle for quicker vigorous activities such as sport play as well as an active contributor to lower-level sustained activities of daily living, though more research is needed.

This muscle rarely has anatomic anomalies. A third head may attach at the origin of the coracobrachialis muscle on the coracoid process¹³ or may arise from the superomedial part of the brachialis muscle beneath the brachial artery, attaching to the bicipital aponeurosis and the medial side of the tendon of insertion.¹

2.1. Innervation and Vascularization

The musculocutaneous nerve, arising from the lateral cord of the brachial plexus and spinal nerve roots C5 and C6, innervates the biceps brachii muscle after it passes through or over the coracobrachialis muscle. A separate branch of the musculocutaneous nerve innervates each head of the muscle.¹

The biceps brachii muscle receives its vascular supply primarily via multiple vessels originating from the brachial artery. It also receives some vascularization from the anterior humeral circumflex artery and the deltoid branch of the thoracoacromial artery; however, a great variation in vascularization has been identified.¹

2.2. Function

Due to its attachment sites, the biceps brachii muscle acts at the glenohumeral, humeroulnar, and humeroradial joints, as well as the proximal radioulnar articulation that lies within the elbow joint capsule. The fact that this muscle has two heads and spans three joints helps explain the complexity of its functions. The biceps brachii muscle functions to flex the elbow^{1, 5, 14–17} and to supinate the forearm when the elbow is partially flexed.^{15, 18} The biceps brachii muscle functions at the shoulder to assist in flexion,^{1, 15, 17} to assist in abduction of the shoulder when the arm is externally rotated (long head),¹⁷ to assist in horizontal adduction of the arm (short head),¹ to pull the humerus down to the side of the body from an elevated position, and to seat the head of the humerus in the glenoid fossa to counteract superior translation from the deltoid (long head).^{1, 5, 17}

During elbow flexion, the two heads of the biceps brachii, the brachialis, and the brachioradialis muscles distribute a sustained forearm flexion load that is irregular and variable.¹⁴ Earlier research suggested that electrical activity is most vigorous in the biceps brachii muscle during flexion at the elbow when the forearm is supinated but is markedly inhibited when the forearm is pronated.^{14, 19} Recent research of muscle activity during elbow flexion demonstrates no significant changes with any hand position for the biceps brachii muscle. In contrast, significant differences in the contribution of the brachioradialis muscle were found during elbow flexion in the pronated, supinated, and neutral hand positions.²⁰ Elbow flexion can still be achieved by the brachialis and brachioradialis muscles if atrophy of the biceps brachii muscle is present.

Support from the biceps brachii muscle is needed at the shoulder to keep the head of the humerus seated in the glenoid cavity and to resist the upward translation of the humerus by the deltoid muscle. When the distal attachment (forearm) is fixed, the biceps brachii muscle flexes the elbow by moving the humerus toward the forearm, as in a pull-up.^{21, 22}

The biceps brachii muscle also functions as a synergist to the supinator muscle to reinforce fast supination or forceful supination of the forearm against resistance.¹⁸ When electrically stimulated, the supination force supplied by the biceps brachii muscle is strongest when the elbow is held in a flexed position.^{16, 19} With the elbow flexed, motor unit activity in the biceps brachii muscle appears during resistance to supination but disappears when the elbow is fully extended.¹⁴

Each head of the biceps brachii muscle can also function independently of one another when abducting and adducting the shoulder. The long head of the biceps brachii muscle is active during both flexion and abduction of the shoulder.⁵ However, it assists with abduction only when the glenohumeral joint is externally rotated with the forearm in a

supinated position.¹⁴ During shoulder flexion, both heads of the muscle contribute to the movement but the long head is more active than the short head.¹⁴ The short head assists with horizontal adduction of the shoulder due to its attachment at the coracoid.¹

The long head also affords increased stability of the glenohumeral joint by providing static restraint to superior migration of the humeral head. This role is primarily passive as active contraction only slightly depresses the humeral head.²³ The static contribution is dependent on the positioning of the tendon within the bicipital groove, which is supported by the biceps brachii pulley mechanism. Tears in the rotator cuff muscles can affect the long head tendon position in the groove due to their role in the biceps brachii pulley mechanism. The biceps brachii tendon is not able to provide a contribution to glenohumeral stability when rotator cuff tears are present. The long head tendon is vulnerable to compression under the acromion and at its attachment to the labrum where it can be avulsed.²

The biceps brachii muscle often performs lengthening eccentric contractions during activities of daily living (eg, when one is required to lower a load from torso level down to the floor) as well as during sports play.¹ During eccentric contractions, the muscle fibers contract while the muscle lengthens. This kind of contraction can cause an acute overload to the muscle that may lead to TrP formation, particularly during sports activities or strengthening exercises. Biceps–labral complex injuries occur more commonly in young athletes and within older manual laborers.

Overload and injury commonly occur in sports activities such as baseball pitching, softball, tennis, swimming, volleyball, and other overhead activities.²⁴ Unusually vigorous motor unit responses of the biceps brachii muscle appear near the end of the tennis serve²⁵ and during the deceleration phase of a baseball pitch. When playing basketball, the muscle is active when blocking a shot or performing a layup. Interestingly, minimal motor unit activity develops during the tennis forehand drive, batting a baseball, or during the golf drive.²⁵ Ilyes et al conducted an EMG analysis of shoulder and upper extremity muscles in five conditions comparing professional javelin throwers with a control group and found the biceps brachii muscle to be moderately active during pulling with the shoulder in 45° flexion and elbow fully extended, and during pushing with the shoulder in a neutral position and the elbow flexed to 90° (45%-55% of maximum volitional contraction [MVC]). During shoulder elevation to 140° in the plane of the scapula, they found the biceps brachii muscle to be moderately active in the control group (58% MVC) and maximally active in the professional athletes (71% MVC).²⁶ During a goal-oriented slow throw, the biceps brachii muscle was minimally active in both the groups, and during a fast throw the biceps brachii muscle was maximally active in both the groups (87% MVC).

Conte et al investigated the EMG activity of the upper extremity, shoulder, and trunk muscles during the use of both a touch pad and an external mouse while utilizing a laptop computer. They found a greater activity in the biceps brachii and triceps brachii muscles while utilizing the touch pad against the external mouse. They found that the touch pad required a greater degree of movement accuracy and stabilization than the external mouse.

They concluded that frequent laptop computer users should utilize an external mouse instead of a touch pad to decrease muscle overload.²⁷

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 30-1 grossly represents the functional unit of the biceps brachii muscle.²⁸

Box 30-1 Functional unit of the biceps brachii muscle

Action	Synergists	Antagonist
Elbow flexion	Brachialis Brachioradialis	Triceps brachii Anconeus
Forearm supination	Supinator	Pronator teres Pronator quadratus

In addition, the biceps brachii muscle is synergistic with the anterior deltoid muscle during shoulder flexion, and the middle deltoid and the supraspinatus muscles when abducting the arm at the shoulder. The coracobrachialis, the clavicular head of the pectoralis major, and the latissimus dorsi muscles act with the short head of the biceps brachii muscle to adduct the arm at the shoulder.

The shoulder adductors, subscapularis, latissimus dorsi, teres major, coracobrachialis, and pectoralis major muscles, act as antagonists to glenohumeral abduction. The supraspinatus, middle deltoid, and shoulder abductor muscles counteract adduction of the shoulder performed by the short head of the biceps brachii muscle.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the biceps brachii muscle are usually found in the midportion of the muscle but can be located anywhere throughout the length of the muscle. They refer pain upward over the biceps brachii muscle and over the anterior deltoid region of the shoulder.²⁹ Occasionally, pain is also located in the suprascapular region (Figure 30-2). Biceps brachii TrPs may also refer less-intense pain downward in the antecubital space.

Figure 30-2. Referred pain pattern (essential zone is solid red, spillover zone stippled red) of TrPs in the right biceps brachii muscle.

Experimental injection of 6% sodium chloride solution into the biceps brachii tendon at the antecubital space in 10 healthy subjects caused pain that was referred locally and also proximally over the biceps brachii muscle, including the acromion in one case. Other phenomena that referred distally to some part of the volar forearm and hand included deep tenderness, erythema, paresthesia, pallor, and a feeling of weakness.³⁰

3.2. Symptoms

Biceps brachii TrPs cause pain that is superficial in the front of the shoulder and may travel down the front of the upper arm over the length of the muscle. Pain may also be present in front of the elbow at the crease. Unlike the infraspinatus muscle, biceps brachii TrP pain is not described as “deep” in the shoulder joint and spares the side of the shoulder. Pain often increases during the elevation of the arm above the shoulder level either to the side or in front of the body.³¹

Tenderness may be present over the upper portion of the front of the shoulder in the area of the biceps brachii tendon. Diffuse aching over the front of the upper arm that rarely includes the elbow and weakness with pain on raising the arm above the head are also symptoms of biceps brachii TrPs. The patient may feel snapping or grating sounds in the upper portion of the shoulder when reaching the arm out to the side. Aching and soreness may be present in the upper shoulder and neck in the region of the upper trapezius muscle.

In contrast to patients with TrPs of the infraspinatus muscle, the patient with biceps brachii TrPs can lie comfortably on the affected side and can reach behind the waistline without pain.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper examination of the biceps brachii muscle, the clinician should assess upper extremity posture in standing with arms at the side (elbow carrying position should be noted), shoulder girdle posture, active and passive ranges of motion of the elbow and the forearm, muscle activation patterns, and scapulohumeral rhythm. To identify TrPs in the biceps brachii muscle that may be limiting the range of motion and thus influencing dysfunction, the clinician should identify the limited range of motion by performing a specific range of motion testing for all parts of the biceps brachii muscle. The bicep brachii muscle crosses three joints and it is therefore difficult to identify length deficits in the muscle or restricted elbow or shoulder motion due to the presence of TrPs. The muscle should be lengthened across all three joints simultaneously to accurately test for abnormal tension of the muscle fibers. The biceps-extension test (Figure 30-3) can be used to evaluate the length of the long head of the biceps brachii muscle. With the patient seated in a low-backed chair and leaning back to stabilize the scapula against the backrest, the patient's arm is abducted to about 45° (Figure 30-3A). With the clinician's hand stabilizing the shoulder, the elbow is then fully extended and the forearm pronated to stretch the muscle across the elbow (Figure 30-3B). Finally, without letting the arm internally rotate at the shoulder, the arm is moved posteriorly into extension. Normally, the arm achieves a fully extended position (Figure 30-3B). If the muscle has been shortened by TrPs, the elbow flexes to relieve tension caused by the increased stretch across the shoulder joint (Figure 30-3C). This compensatory flexion of the elbow indicates a shortened biceps brachii muscle. Stretching the involved biceps brachii muscle by passively extending the forearm causes pain.

Figure 30-3. Biceps-extension Test for muscle shortening due to TrPs in the biceps brachii muscle. A, Initial test position with the forearm pronated, elbow straight, and arm abducted to about 45°. B, Normal end test position. C, Limited extension at the elbow due to biceps brachii length deficit.

The patient may report a sudden painful “catch” in the shoulder when abducting the arm in slight extension to 15° or 20°, and careful examination may reveal tenderness or enthesopathy near the attachment of the long head of the biceps brachii tendon to the glenoid labrum. When the tender area of enthesopathy presses against the acromion during the elevation of the arm, the patient experiences pain that is commonly referred to as an “impingement syndrome.” The tendon of the long head can be palpated against the head of the humerus only with the arm in external rotation. Otherwise, it is covered by the acromion.

Hidalgo-Lozano et al³² identified that patients diagnosed with shoulder impingement had a higher prevalence of active and latent TrPs in the biceps brachii muscle than asymptomatic control subjects. Patients with TrPs in the biceps brachii and subscapularis muscles (active or latent) had higher levels of pain with an active elevation of the shoulder when compared with patients without TrPs in those muscles. When TrPs in the long head of the biceps brachii muscle were inactivated, patients experienced a spontaneous resolution of their pain and restoration of a full range of motion at the shoulder.

Muscle-specific resisted testing should be performed to identify impairments in muscle function and reproduction of painful symptoms. Inhibition of the biceps brachii and brachialis muscles can be identified by strength testing of elbow flexion in forearm supination and then pronation, while the elbow is extended. The biceps brachii muscle activation pattern remains the same with the forearm supinated, pronated, or in the neutral position, whereas the brachioradialis muscle activation varies depending on the hand position. Brachialis muscle function increases with forearm pronation.²⁰

Accessory joint motion of the shoulder, elbow, and radioulnar joints should be manually tested when biceps brachii TrPs are suspected. Specifically, treatment of the acromioclavicular and sternoclavicular joints may be necessary to establish a free movement of the entire shoulder complex, if pathologic arthrokinematics are a contributing factor to biceps brachii TrPs.

3.4. Trigger Point Examination

To examine the biceps brachii muscle, the patient is positioned supine with the scapula flat on the examining table or seated with the elbow supported on a well-padded surface and with the trunk stabilized against the back of the chair. Palpation for TrPs in the biceps brachii muscle should include the evaluation of the whole muscle including both the short and long heads. To slacken the biceps brachii muscle slightly, the elbow is flexed to about 15° and the forearm is supinated and supported. Cross-fiber flat or pincer palpation is used to screen each head of the biceps brachii muscle to identify taut bands and TrPs (Figure 30-4A and B). Palpation that is too deep may identify TrPs in the underlying brachialis muscle, which are more likely to refer pain to the thumb.

Figure 30-4. Examination of the biceps brachii muscle for TrPs with the patient supine. A, Cross-fiber pincer palpation of the biceps brachii muscle, long head. B, Cross-fiber pincer palpation of the biceps brachii muscle, short head.

For cross-fiber pincer palpation, the elbow is flexed another 15° to further slacken the muscle. The muscle bellies of both heads are then lifted away from the underlying brachialis muscle at mid-muscle, and the tension in the muscle is adjusted by modifying the degree of elbow flexion to optimize the distinction between a taut band and the

surrounding normal muscle. Then, the biceps brachii fibers are rolled between the fingers and thumb to accurately localize any taut bands, TrPs, and areas of spot tenderness. The precise location of the TrP is obtained by pressing along the length of a taut band to pinpoint the spot of greatest tenderness and firmness. Application of pincer palpation with a strong snapping movement across a taut band at the point of maximum tenderness may elicit a visible and palpable local twitch response.

Bron et al³³ assessed the prevalence of muscles with TrPs in 72 patients with chronic nontraumatic unilateral shoulder pain. They found the infraspinatus (93%) and the upper trapezius (94%) muscles with the highest prevalence of TrPs. They also found 51% of the patients had TrPs in the biceps brachii muscle.

Range of motion testing for the biceps brachii muscle can also be used to screen for TrPs. While passive movements of the arm and forearm are being performed, the clinician can ask the patient where he or she feels tension and then palpate there for a taut band that may be limiting the range of motion and thus producing dysfunction.

Bron et al³³ established that the most reliable criteria for identifying TrPs in the biceps brachii muscle were palpation of a taut band and the presence of referred pain on palpation. The local twitch response, jump sign, and identification of a nodule within the taut band did not demonstrate a good reliability despite an easy accessibility of the muscle for palpation.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the biceps brachii muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position(s) for an extended period of time.

Pain generated by biceps brachii TrPs is often activated and perpetuated by activities that involve forceful or vigorous elbow flexion and supination, repetitive lifting of heavy objects with the forearm supinated, and sudden overstretching of the biceps brachii muscle into extension.

Activities such as a strong backhand tennis stroke performed with the elbow straight and the forearm supinated to apply topspin can cause overstress to the biceps brachii muscle. Other activating movements could include sudden lifting with the arm extended such as lifting the hood of a car or lifting boxes at arm's length. Others are unaccustomed vigorous or repeated supination motions including using a screwdriver and a shoveling snow. A single episode of heavy elbow-flexion load as in using an electric hedge clipper can also lead to the overuse of the muscle and TrP formation. Sudden overstretching of the muscle can cause traumatic TrP formation. This may occur when catching a fall on an outstretched hand commonly referred to as a fall on an outstretched hand (FOOSH) injury. Investigators found that the biceps brachii muscle achieved peak %MVC prior to

the time of peak impact force.³⁵

Frequently repeated activities that can also activate and perpetuate biceps brachii TrPs include playing the violin and hard serving in competitive tennis. Violin playing positioning causes combined elbow flexion with supination causing prolonged activation of the biceps brachii muscle.

Anatomically, the biceps brachii muscle has expansions that insert into the brachial and antebrachial fascia and the bicipital aponeurosis.^{1,6} All the flexor muscles of the arm have insertions into a continuous fascial expansion that extends throughout the anterior arm.^{6,7} When tension is applied proximally to the bicipital aponeurosis to simulate a biceps brachii muscle contraction, lines of force are generated within the muscular fascia that mirror the direction of the stretched muscle fibers. These lines of force form an anatomic continuity between the muscular components involved in the flexion of the upper limb. Stecco et al⁷ hypothesize that these fascial connections provide reciprocal feedback between the fascia and the muscles and may be used to facilitate peripheral motor control.⁶ The fascia can perceive tension produced by a muscle and transmit it to a distance, informing the distal muscle about the state of contraction of the proximal muscle. It is known that the fascia is innervated by proprioceptive nerves and that mechanoreceptors are sensitive to tension. In the absence of normal physiologic elasticity, the fascial receptors may be in an active state even at rest. Further stretching of the fascia by muscle contraction may trigger overstimulation of these receptors, causing them to become algoreceptors, propagating nociceptive signals even with normal stretch. This may contribute to the origin of myofascial pain syndromes, the formation of TrPs, and referred pain patterns throughout the upper arm.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.³⁶ Therefore, musculature in the referred pain areas for each involved muscle should be considered. Release of the TrP in the muscle referring pain often allows for an immediate decrease in the pressure pain threshold of the associated TrPs.³⁶

The biceps brachii muscle may develop associated TrPs induced by TrPs in the infraspinatus muscle.³⁷ Inactivation of the infraspinatus TrPs is essential for prolonged biceps brachii muscle relief and may be all that is required to inactivate the biceps brachii TrPs.

Associated TrPs commonly develop in the synergistic brachialis and supinator muscles, and also in the antagonistic triceps brachii muscle. Eventually, the anterior deltoid, the supraspinatus, and the upper trapezius muscles succumb to the added stress on these remaining muscles of the biceps brachii's functional unit. Finally, the coracobrachialis muscle may develop associated TrPs.

4.3. Associated Pathology

Cervical radiculitis in the C5 or C6 nerve roots often result in the formation of TrPs in those muscles innervated by the same nerve roots. Patients with C5-C6 radicular pain often report having deep anterior shoulder pain, anterolateral shoulder pain, brachium and forearm pain, and pain into the radial aspect the hand and lateral 2½ digits. Wainner and colleagues³⁸ identified a test item cluster to determine the likelihood that a patient is presenting with a cervical radiculitis (radiculopathy). The following predictor variables were identified: a positive Spurling sign, cervical rotation less than 60° to the same side, positive cervical compression test, relief of symptoms with axial distraction, and a positive neurodynamic upper limb test. Patients presenting with four of these positive variables have a 90% posttest probability of cervical radiculitis (radiculopathy). Patients with three positive variables have a 65% posttest probability of cervical radiculitis (radiculopathy). Refer to Chapter 33 for more clinical considerations.

The referred pain and referred deep tenderness characteristic of biceps brachii TrPs can easily lead to a number of commonly mistaken diagnoses and a careful evaluation of the shoulder is necessary to differentiate between glenohumeral pathology and biceps brachii TrPs. Some of these diagnoses include bicipital tendinitis, subdeltoid bursitis, bicipital bursitis, and glenohumeral arthritis.

Deep tenderness to palpation of the long head of the biceps brachii tendon in the area of pain referred from TrPs in the biceps brachii muscle may be mistaken for dysfunction of the biceps–labral complex or subdeltoid bursitis. The presence of painful biceps brachii tendon instability can be established by a palpable and painful click as the tendon of the long head of the biceps brachii muscle slides over the lesser tubercle when the fully abducted and externally rotated arm is moved slowly into internal rotation and back into external rotation.¹⁵ Biceps brachii tendon instability is unlikely to be related to biceps brachii TrPs. If dysfunction of the biceps–labral complex is suspected, specific diagnostic testing should be carried out to determine the structures at fault. Similarly, tenderness elicited by deep palpation over the deltoid muscle but referred from biceps brachii TrPs may be misidentified as subdeltoid bursitis. Refer to orthopedic examination textbooks and journal articles for more on these conditions.

5. CORRECTIVE ACTIONS

Trigger points in the biceps brachii muscle can be treated through activity modification to avoid excessive muscle strain, self-pressure release, and self-stretch techniques. The patient with biceps brachii TrPs should avoid habitual, sustained, or repetitive motions that overload the biceps brachii muscle by not carrying heavy objects such as grocery bags or a briefcase with the elbow fully straightened or slightly bent. The patient should also avoid lifting and carrying objects with the forearms supinated. Placing the forearm in a neutral position with the thumb up (Figure 30-5A) or pronating the forearm by turning the palm down (Figure 30-5B) when lifting will transfer some of the load from the biceps brachii muscle to the brachioradialis, brachialis, and supinator muscles. The muscle activation of the biceps brachii muscle does not change, but the muscles that assist with this function are

activated more strongly.²⁰

Figure 30-5. Carrying an object with different forearm positions. A, Forearm in neutral. B, Forearm pronated.

Proximal forearm pain experienced when the forearm is flexed at the elbow with supination but not felt during flexion with pronation, may be attributed to bursitis of the bicipital bursa located at the radial attachment of the biceps brachii muscle or to active TrPs in the biceps brachii or supinator muscles. Trigger points and bursitis can also occur simultaneously and both should be considered when evaluating a patient who reports this type of pain.

The patient should avoid sleeping with the elbow tightly flexed by placing a small pillow in the crook of the elbow or by wrapping a small towel loosely around the elbow to avoid bending the elbow past 90° (Figure 30-6). This simple technique prevents the prolonged shortening of the muscle while sleeping.

Figure 30-6. The correct sleeping position for a patient with TrPs in the left biceps brachii muscle.

The patient may inactivate a biceps brachii TrPs by applying self-pressure release using a pincer palpation technique (Figure 30-7). Trigger point compression alone has been found to be effective in treating chronic shoulder pain. Pressure should be painful but bearable, and it can be applied for bouts as short as 15 seconds in duration to be effective.³⁹ The patient can perform the examination for TrPs in the biceps brachii muscle as mentioned earlier, and then apply pressure over the TrP while the arm is allowed to relax. The elbow can be gently flexed and extended in turn to help facilitate release.

Figure 30-7. Self-pressure release of TrPs using a pincer palpation technique.

Following treatment for inactivation of TrPs in the biceps brachii muscle, the patient should gently stretch both heads of the muscle daily by doing a self-stretch in a doorway (Figure 30-8A and B). The patient externally rotates the arm at the shoulder joint and pronates the forearm to hook the fingers, thumb down, against the doorjamb. With the hand slightly below the shoulder level, the patient rotates the torso away from that arm, applying a gentle traction to the straightened elbow (Figure 30-8A and B). Bouncing and jerking should be avoided to achieve a steady passive stretch of the muscle. Slow exhalation during the stretch enhances relaxation and improves tension release in the muscle.

Figure 30-8. Self-stretch of the biceps brachii, anterior deltoid, and coracobrachialis muscles. A, The patient starts by placing their hand on the door frame in the lower position. B, If no stretch is felt, the hand can be placed higher on the door frame just below shoulder height. This stretch should not be performed with the hand above the shoulder height. Slow exhalation during the stretch phase enhances the effectiveness of this exercise.

Brachialis Muscle

“Snuffbox Scourge”

Joseph M. Donnelly and Leigh E. Palubinskas

1. INTRODUCTION

The brachialis muscle is a powerful one-joint elbow flexor that originates proximally from the shaft of the humerus and attaches distally to the ulna. This orientation allows the brachialis muscle to function independently from forearm rotation unlike the biceps brachii muscle. The brachialis muscle is innervated by the musculocutaneous nerve. Trigger points (TrPs) in the brachialis muscle chiefly refer pain to the dorsum of the carpometacarpal joint at the base of the thumb and often elicit pain reports in the region of the anterior upper arm and the antecubital space. Trigger points in the brachialis muscle can be aggravated by holding the elbow in positions of flexion for prolonged periods or by repetitive overload of the muscle during activities such as lifting with the elbows flexed. Brachialis TrPs most often occur in conjunction with those found in the biceps brachii muscle. Evaluation of the patient should include testing to rule out C5-C6 radicular pain, lateral epicondylalgia, De Quervain’s tenosynovitis, carpal tunnel syndrome, and radial nerve entrapment. The patient with TrPs in the brachialis muscle should be instructed to avoid repetitive elbow flexion and lifting techniques that foster overload stress to the brachialis muscle. Sleeping postures should be altered to avoid prolonged positioning of the muscle in a shortened flexed posture. To independently manage pain related to the brachialis muscle, the patient may perform TrP self-pressure release and self-stretch techniques.

2. ANATOMIC CONSIDERATIONS

The brachialis muscle originates from the distal half of the anterior surface of the shaft of the humerus and from the medial and lateral intermuscular septa (medial more than lateral). The proximal attachment reaches the distal attachment of the deltoid muscle (Figure 31-1). The muscle fibers converge into a thick broad tendon that attaches to the ulnar tuberosity and the anterior surface of the coronoid process on the proximal end of the

ulna.¹

Figure 31-1. Attachments of the right brachialis muscle to the humerus above, and ulna below. The cut end of the overlying biceps brachii tendon appears below. The deltoid muscle, above, also has been cut for clarity.

Anatomical variations of the brachialis muscle have been identified but are quite rare. The brachialis muscle may be divided into two or more parts. It may be fused with the brachioradialis, pronator teres, or biceps brachii muscles. In some cases, it may send tendinous slips to the radius or bicipital aponeurosis.¹ Anatomical variations can also include accessory brachialis muscles arising from the distal portion of the muscle.²⁻⁴ In two of these reported cases,^{2,4} the accessory muscle crossed over the median nerve creating a point of possible entrapment. In a third case,³ the brachialis muscle split into two distally, encompassing the radial nerve. Capsular fibers from the deepest part of the brachialis muscle may insert into the anterior joint capsule of the elbow.^{4,5} Originally, it was thought that these fibers may cause retraction of the elbow joint capsule to prevent impingement when the elbow flexes.⁴ This notion has since been refuted and these capsular attachments are believed to serve as an additional attachment site for the muscle with no functional significance.⁵ Proximally, variation of the muscle origin is less frequent; however, one study found the brachialis muscle attached by a strong tendon to the lateral lip of the intertubercular sulcus close to the deltoid tuberosity.⁶ This tendinous insertion did not appear to play a functional role, and it has been speculated that it could be used for reconstructive surgeries.

2.1. Innervation and Vascularization

The brachialis muscle is innervated by the musculocutaneous nerve via the lateral cord of the brachial plexus arising from the C5 and C6 nerve roots. The musculocutaneous nerve supplies a branch to the shoulder joint and then passes through the coracobrachialis muscle and between the biceps brachii and brachialis muscles, sending branches to both before descending through the cubital fossa.¹

A small inferolateral part of the brachialis muscle is typically innervated by the radial nerve via the posterior cord from the C7 nerve root.^{1,7} Radial nerve innervation is present in approximately 67% to 100% of the population.⁸⁻¹³ This variation in findings is thought to be due to race, sample size, and research techniques.¹² Originally, it was believed that the radial nerve served only a sensory function, but more recent research has confirmed the radial nerve provides motor innervation as well.^{10,-12,14}

In some instances, the median nerve may also innervate the brachialis muscle. This variation is typically observed when there is damage to the musculocutaneous nerve, but in some cases, the brachialis muscle has been found with triple innervation from the musculocutaneous, radial, and median nerves.^{12,15,16}

Vascular supply to the brachialis muscle is primarily provided by the brachial artery (superiorly) and the superior ulnar collateral artery (inferiorly). The brachialis muscle may also receive vascularization from the inferior ulnar collateral artery or the profunda brachii

artery.¹

2.2. Function

Due to its ulnar attachment, the brachialis muscle performs only one motion: flexion at the elbow joint with the forearm either pronated or supinated.^{1,17–21} It is the “workhorse” of the elbow flexors, having the greatest cross section of all muscles near the elbow.^{1,22} Like the deltoid muscle, it shows no activity when the dependent arm is heavily loaded with weights.¹⁷ There is a fine interplay between the biceps brachii, the brachialis, and the brachioradialis muscles during resisted forearm flexion. The interplay shows striking variability on repeated trials.¹⁷

When the proximal attachment (humerus) is fixed, the brachialis muscle moves the forearm toward the humerus. With the distal attachment (ulna) fixed, it moves the humerus toward the forearm, as in pull-up exercises.²⁰ The brachialis muscle often contracts eccentrically to decelerate and control the lowering of heavy objects.

During the act of driving a car, the brachialis muscle demonstrates a relatively constant low level of activity and only occasionally showed short bursts of more intense activity.²³

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 31-1 grossly represents the functional unit of the Brachialis muscle.²⁴

Box 31-1 Functional unit of the brachialis muscle

Action	Synergists	Antagonist
Elbow flexion	Biceps brachii Brachioradialis Pronator teres	Triceps brachii Anconeus

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Pain from brachialis TrPs chiefly refers to the dorsum of the carpometacarpal joint at the

base of the thumb and to the dorsal web of the thumb (Figure 31-2).²⁵ The referred pain pattern may also include the anterior aspect of the upper arm and the antecubital space.

Figure 31-2. The pain pattern (essential portion, solid red; spillover portion, stippled red) that is referred from TrPs in the right brachialis muscle. Taut bands associated with mid-muscle TrPs may cause entrapment of the radial nerve.

Pain referral from mid-fiber TrPs may cover the antecubital space. The pain that occasionally extends upward over the deltoid muscle is more likely to arise from the most proximal TrPs in the brachialis muscle (Figure 31-2).²⁶

3.2. Symptoms

Trigger points in the brachialis muscle are often associated with diffuse soreness of the thumb. The patient's main report of pain is typically present when the joint is at rest and may be aggravated with an active thumb motion. The patient may also report pain in the crease of the elbow and in the anterior aspect of the shoulder and upper arm.

Pain in the anterior shoulder that is caused solely by brachialis TrPs are not associated with impairment of the shoulder motion. Because the brachialis muscle is a one-joint muscle that crosses the elbow, decreased flexibility or pain with muscle activation does not have an effect on the glenohumeral joint function.

Pain symptoms in the carpometacarpal thumb joint may arise from radial nerve entrapment due to TrPs in the brachialis muscle. Symptoms caused by the entrapment of the superficial sensory (cutaneous) branch of the radial nerve include dysesthesia, tingling,

and numbness at the dorsum of the thumb. The aching pain of referred TrPs and the symptoms of radial nerve entrapment are both experienced in the thumb and may be relieved by inactivating brachialis TrPs.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the patient's progression as symptoms improve or change. Pain referred from brachialis TrPs is increased by full passive extension of the elbow, although limitation of motion is not often a report. The range of elbow extension may be restricted by only a few degrees and may be detectable only by comparison with the other side or by improvement after treatment. Active motion of the thumb in the pain referral zone is typically painful, but active movement of the elbow is not.

Weakness or inhibition of the biceps brachii and brachialis muscles can be distinguished by testing the strength of the elbow flexion in supination and then in pronation of the forearm while the elbow is extended. This change in position has no effect on brachialis muscle strength because it attaches to the ulna, but historical theory states that the biceps brachii muscle may demonstrate functional weakness with forearm pronation by placing it in a lengthened position. A recent research utilizing EMG analysis of the biceps brachii and brachioradialis muscles during elbow flexion with altering the hand positions demonstrates no change in biceps brachii muscle activation with a change in the hand position.²⁷ Therefore, it may be more beneficial to test resisted forearm supination to differentiate the biceps brachii muscle from the brachialis muscle.

Radial nerve compression is indicated when a tingling in the thumb results from the pressure exerted on the region where the nerve exits the musculospiral groove and pierces the lateral intermuscular septum (Figure 32-2). Pressure should be applied about mid-arm, just below the dimple that marks the apex, or the distal end, of the triangular bulge produced by the deltoid muscle. In this area the radial nerve passes between the brachialis and the brachioradialis muscles, creating a possible site of compression.²⁸

If a limited elbow range of motion is present, the humeroulnar, humeroradial, and proximal radioulnar joints should be examined for accessory joint motion and should be treated, if restricted.²⁹

3.4. Trigger Point Examination

When evaluating for TrPs in the brachialis muscle, the patient should be positioned with the elbow flexed between 30° and 45° and the forearm in a comfortable resting position. If there is increased tension in the biceps brachii muscle the patient's forearm can be placed in a supinated position to slacken the biceps brachii muscle. The bulk of the biceps brachii muscle should be pushed aside, medially, to palpate the underlying brachialis TrPs (Figure 31-3). The biceps brachii muscle has more slack if the forearm is placed in supination and

is relaxed. Brachialis TrPs are typically located in the distal half of the muscle (Figure 31-2) and are likely to refer pain to the thumb and sometimes to the front of the elbow. Trigger points may be located deep to the lateral edge of the undisplaced biceps brachii muscle, but others are found toward the middle of the brachialis muscle, sometimes under the biceps brachii muscle. The more proximal TrPs, which refer pain to the upper arm and anterior aspect of the shoulder, are covered by the biceps brachii muscle, making identification and palpation more difficult.

Figure 31-3. Examination of the brachialis muscle for TrPs by pushing the biceps brachii muscle aside in a medial direction to perform cross-fiber flat palpation to identify the TrPs. The biceps brachii muscle has additional slack if the forearm is supinated rather than pronated as shown here.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

Trigger points may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³⁰ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. Brachialis TrPs can be activated and can be perpetuated by repeated and prolonged overload of elbow flexion during heavy lifting. Examples of stress overloads are holding a power tool, carrying groceries, holding a baby, picking up children, and playing a violin or guitar with the forearm supinated such that the biceps brachii muscle is shortened and inhibited. Computer work where the arms are held out for long periods of time requires a static low-level contraction of the brachialis muscle in both arms and can lead to activation and perpetuation of TrPs in the brachialis muscle.

Elbow pain associated with TrPs in the brachialis muscle may be misdiagnosed as lateral epicondylalgia or “tennis elbow.” With this condition, brachialis muscle involvement tends to develop together with that of the biceps brachii muscle after initial activation of TrPs in the supinator muscle (Chapter 36). The repetitive nature of the tennis swing during a match play or practice is another example of repetitive overload to the elbow flexors and supinators. This phenomenon is especially observed with forehand ground strokes in tennis.

Recent research indicates that brachialis TrPs may also form as a result of rotator cuff pathology. Suh et al³¹ found brachialis TrPs to cause anterior shoulder pain in a sample of patients with rotator cuff pathology, whose anterior shoulder pain did not respond to subacromial injections of local anesthetics or steroid. Palpation of the brachialis muscle revealed TrPs in 23 of the 24 patients who did not respond to injection. It is hypothesized that the biceps brachii muscle may perform a greater role as a shoulder stabilizer in this population, causing increased overload pressure on the brachialis muscle during elbow flexion. The one-joint nature of the brachialis muscle also causes it to be more involved in posture, which may be distorted due to shoulder pain and a change in scapula position. Each of these would lead to increased overload pressure through the muscle, which may promote TrP formation.³¹

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas of TrPs.³² Therefore, musculature in the referred pain areas for each involved muscle should also be considered. Associated TrPs of the brachialis muscle can develop in the deltoid, biceps brachii, supinator, brachioradialis, and the adductor and opponens pollicis muscles. The brachialis muscle is also likely to be involved when the biceps brachii, brachioradialis, or supinator muscles have TrPs.

4.3. Associated Pathology

Anterior shoulder pain in the region of referred pain from brachialis TrPs may also be caused by bicipital or supraspinatus tendinitis, or by TrPs of the infraspinatus, anterior deltoid, posterior deltoid, and/or latissimus dorsi muscles. These conditions should be ruled out with a thorough examination of the shoulder region. Active movement of the shoulder should not be painful if brachialis TrPs are the sole source of pain and dysfunction.

Cervical radicular symptoms from the C5 or C6 nerve roots may cause pain in the anterior shoulder, anterolateral upper arm, forearm, and the radial portion of the wrist and hand encompassing the thumb and index finger. These symptoms could easily be confused with the referral pattern associated with brachialis TrPs (Figure 31-2). A test item cluster has been identified to rule out cervical radicular pain and/or radiculopathy (refer to Chapter 33).³³

As mentioned earlier, lateral epicondylalgia (tennis elbow) is often the result of TrPs in the biceps brachii, supinator, and potentially, the brachialis muscles. Trigger points should

be considered in the absence of tenderness over the lateral epicondyle of the humerus.

Other hand pathologies should be considered when evaluating the patient with thumb pain. Carpal tunnel syndrome may cause pain perceived as isolated over the thenar eminence. De Quervain's tenosynovitis can also cause pain in the region of the carpometacarpal joint. If TrPs are responsible for the pain, Finkelstein's test yields different results if performed with the elbow extended or flexed. Because the abductor pollicis longus and extensor pollicis brevis tendons do not cross the elbow, the position of the elbow joint should not change the patient's pain if De Quervain's tenosynovitis is the cause.

Entrapment of the radial nerve should also be considered as part of the differential diagnosis. Symptoms of nerve entrapment include numbness, hypoesthesia or hyperesthesia, and dysesthesia. These symptoms, like the referred pain from brachialis TrPs, appear over the dorsum of the thumb and its adjacent web space. An entrapment of the sensory branch of the radial nerve can be caused by a TrP, usually in the lateral border of the brachialis muscle, which produces a taut band of muscle fibers extending to the level where the radial nerve exits the musculospiral groove and pierces the lateral intermuscular septum (Figure 32-2). These symptoms of entrapment caused by brachialis TrPs are relieved by the release of the TrP, which feels like a palpable knot in the lateral border of the muscle, just proximal to the nerve. A resultant resolution of the taut band and the relief of nerve entrapment symptoms strongly suggest that muscle shortening associated with the TrPs produced the nerve compression.

5. CORRECTIVE ACTIONS

To prevent stress overload of elbow flexion, the patient should lift only light or moderate loads with the forearms pronated. This position more readily activates the brachioradialis muscle, avoiding additional load on the brachialis muscle.²⁷ Avoiding repetitive lifting with the elbows flexed also decreases the overload on the muscle.

To avoid immobilizing the brachialis muscle in a shortened position, a towel can be wrapped around the elbow to prevent a prolonged flexed or extended position while sleeping (Figure 30-6). This prevents tension through the muscle. Likewise, the elbow should not be held sharply flexed while talking on a phone. The phone should be switched between hands occasionally, or a speaker function may be utilized. A purse should be held in the fingers with the elbow straight or hung over the opposite shoulder, not hung from the affected forearm with the elbow bent, to avoid prolonged strain through the elbow flexors. When playing a musical instrument that requires bent elbow positioning, like the violin or guitar, the elbow should be allowed to hang down straight at every opportunity.

Patients can perform self-pressure release of TrPs in either the supine or seated position. The patient should support the forearm in a flexed position to slacken the biceps brachii muscle and to allow access to the deep brachialis muscle (Figure 31-4). After finding a tender spot, a gentle pressure is applied with either the thumb or a tier of digits for 30 seconds or until the pain decreases. This release may be repeated three to five times as needed. Forceful pressure should be avoided as many nerves travel through this region. If

any numbness or tingling occurs, the position of the thumb or digits should be modified.

Figure 31-4. Self-pressure release of TrPs in the brachialis muscle.

Initially, the arm should be allowed to rest in this position using only the force of gravity to assist post-isometric relaxation without any assistance from the other hand. The patient should then perform a series of contracting and relaxing maneuvers synchronized with respiration to obtain maximum efficacy. During these maneuvers, the patient may also apply firm pressure with the opposite fingers over an identified active TrP. This action may help facilitate the TrP release. After several cycles of post-isometric relaxation, additional release and lengthening may be achieved by gently assisting a stretch into elbow extension (straightening) with the other hand. This process should not be painful, but a sense of stretch tension may be perceived. The patient should do several of these augmented stretches two to three times daily.

Triceps Brachii and Anconeus Muscles

“Elbow Excruciators”

Leigh E. Palubinskas and Joseph M. Donnelly

1. INTRODUCTION

The triceps brachii muscle is commonly overlooked as a source of symptoms for lateral or medial epicondylalgia. It is a three-headed fusiform muscle that occupies the posterior extensor compartment of the upper arm along with the anconeus muscle. The long head of the triceps brachii muscle is biarticular, crossing both the shoulder and the elbow, allowing it to act at both joints. The other heads (medial and lateral) are uniarticular and act only at the elbow. The long and lateral heads of the triceps brachii muscle and the anconeus muscle are innervated by branches of the radial nerve. The innervation of the medial head of the triceps brachii muscle is controversial. It is generally accepted that the muscle is also innervated by the radial nerve, but others have shown that the ulnar nerve innervates the medial head of the triceps brachii muscle. The primary function of the triceps brachii muscle is extension of the elbow. The medial head of the triceps brachii muscle is most active in elbow extension and is considered the “workhorse” of the three heads. The long head of the triceps brachii muscle stabilizes the glenohumeral joint from below by providing a superior force, which counteracts the tendency of the latissimus dorsi and pectoralis major muscles to pull the head of the humerus downward out of the glenoid fossa. It also adducts and extends the arm at the shoulder. The anconeus muscle assists the triceps brachii muscle in elbow extension and acts as an active lateral stabilizer of the humeroulnar joint. Trigger points (TrPs) in the triceps brachii muscle primarily refer pain to the posterior upper arm with referral into the posterior shoulder and upper trapezius muscles proximally. Distally, the referral pattern can encompass the posterior forearm and fourth and fifth digits of the hand. Pain is often localized over the lateral epicondyle and/or medial epicondyle, mimicking the symptoms of tennis and golfer’s elbow, respectively. Trigger points in the anconeus muscle refer to the lateral epicondyle. Triceps brachii and anconeus TrPs are activated by repetitive overuse of elbow extension such as when using forearm crutches, playing tennis, or repeatedly pressing down on a surface. Differential

diagnoses include lateral or medial epicondylitis, olecranon bursitis, and thoracic outlet syndrome. Postural adjustments to support the elbow when performing activities with the arms in front of the body can help prevent TrP formation. Corrective actions include modification of sports activities with a gradual return to sport following treatment; TrP self-pressure release and self-stretch are also effective in releasing TrPs in the triceps brachii muscle.

2. ANATOMIC CONSIDERATIONS

Triceps Brachii

Long Head

The triceps brachii muscle is a three-headed fusiform muscle that fills the majority of the extensor compartment of the upper arm (Figure 32-1A and B). The long head of the triceps brachii muscle crosses both the shoulder and elbow joints. Proximally, it originates from a flat tendon attached to the infraglenoid tubercle of the scapula and blends superiorly with the glenohumeral joint capsule.¹ The muscle travels inferomedially, passing between the teres major and teres minor muscles to form the quadrangular and triangular spaces.^{1, 2} The quadrangular space contains the posterior humeral circumflex artery and the axillary nerve. The subscapularis muscle, teres minor muscle, and glenohumeral joint capsule make up the superior border. The inferior border is defined by the teres major muscle. The medial border is defined by the long head of the triceps brachii muscle, and the lateral border is defined by the humerus. The triangular space contains the scapular circumflex vessels and is defined superiorly by the teres minor muscle, inferiorly by the teres major muscle, and laterally by the long head of the triceps brachii muscle.¹ These spaces and boundaries are important to identify when performing a TrP injection or dry needling.

Figure 32-1. A, Cross section of the right arm just proximal to the level where the radial nerve penetrates the lateral intermuscular septum (the horizontal double arrow and black line in [B] across the muscle indicate the level of cross section). The biceps brachii, brachialis, and anconeus muscles are light red. B, Attachments of the right triceps brachii muscle (two darker reds) seen from behind. The medial (deep) head is dark red and the lateral and long heads are medium red and the anconeus is in light red.

Medial Head

The medial head of the triceps brachii muscle, sometimes referred to as the deep head, originates from the entire posterior surface of the proximal humerus, at the insertion of the teres major muscle and below the radial groove, extending inferiorly just proximal to the trochlea of the humerus.¹ It also originates from the medial humerus and from the lower portion of the lateral intermuscular septum. It covers the posterior humerus both medially and laterally. The medial head of the triceps brachii muscle lies deep against the bone and attaches just above the elbow (Figure 32-2). The lateral and long heads of the muscle overlap it posteriorly. The distal portion of the medial head converges with the common triceps brachii tendon with some muscle fibers inserting directly into the olecranon.¹

Figure 32-2. Posterior view of the triceps brachii muscle with the lateral head cut and reflected, showing the course of the radial nerve, which separates the humeral attachments of the medial and lateral heads of the triceps brachii muscle.

Lateral Head

Proximally, the lateral head of the triceps brachii muscle originates from a flat tendon on the posterior surface of the shaft of the humerus, the lateral intermuscular septum just superior to the radial groove, and posterior to the deltoid tuberosity, extending to the surgical neck of the humerus near the insertion of the teres minor muscle. It bridges the radial nerve and covers much of the medial head of the triceps brachii muscle (Figure 32-1B). The fibers of the lateral head of the triceps brachii muscle converge with the common tendon medially. The medial and lateral heads of the triceps brachii muscle are uniarticular, crossing only the elbow joint.¹

The three heads of the triceps brachii muscle insert distally to the upper surface of the olecranon process of the ulna via a common tendon (Figure 32-1), which begins in the middle of the muscle and consists of a superficial lamina and a deep lamina that join near their insertion. On the lateral side of the olecranon, a band of fibers continue down over the anconeus muscle to blend with the antebrachial fascia.¹

The distribution of fiber types in the triceps brachii muscle has been studied by taking samples of the triceps brachii muscles post mortem.³⁻⁵ Both the lateral head and long head of the triceps brachii muscle had ~60% to 65% fast twitch (type II) fibers and ~40% slow twitch (type I) fibers. However, the medial head was comprised of 60% slow twitch fibers and only 40% fast twitch fibers.³ Samples taken near the surface of the muscle and from deep in the triceps brachii muscles showed no significant difference in this composition.

Anconeus

The anconeus muscle is a small triangular muscle that is partially blended with the triceps brachii muscle posterior to the elbow joint. It originates from the posterior surface of the lateral epicondyle, covers the posterior aspect of the annular ligament, and attaches distally to the lateral side of the olecranon process and to the dorsal surface of the ulna.¹ Fibers of the muscle are also adhered to the lateral aspect of the humeroulnar joint, adding stability to the joint.⁶ An anomalous anconeus epitrochlearis muscle may attach between the medial aspect of the olecranon and the medial epicondyle overlying the ulnar nerve.⁷

The anconeus muscle is composed of ~60% to 67% type I fibers and ~35% type II fibers.⁵ This fiber composition supports the function of the anconeus muscle as an elbow stabilizer rather than a force producing muscle.

2.1. Innervation and Vascularization

The long and lateral heads of the triceps brachii muscle and the anconeus muscle are

innervated by branches of the radial nerve via the posterior cord of the brachial plexus from spinal roots C6, C7, and C8.¹

The innervation of the medial head of the triceps brachii muscle is controversial. Several recent cadaveric studies have identified ulnar nerve innervation in 28% to 61% of samples.^{8–10} This finding is contrary to the generally accepted belief that the muscle is innervated by the radial nerve. It is hypothesized that the high incidence of ulnar nerve innervation may be due to the fact that in these studies the nerve was not traced far enough proximally to make an accurate identification of the nerve.^{11, 12} In addition, the radial and ulnar nerves travel for a distance within the same nerve sheath making conclusive identification of the fibers difficult. Innervation of this muscle remains debatable and no conclusive data from large-scale research studies have confirmed innervation of the medial head of the muscle by either the radial or the ulnar nerve.

The long head of the triceps brachii muscle receives its vascular supply from the axillary artery and the brachial or ulnar collateral arteries. The medial and lateral heads of the triceps brachii muscle receive vascularization primarily from the profunda brachii artery, superior ulnar collateral artery, and a branch of the posterior circumflex artery.¹

The anconeus muscle receives its vascularization via branches of the posterior interosseous recurrent artery.¹

2.2. Function

All parts of the triceps brachii muscle extend the forearm at the elbow joint.^{13–19} The medial (deep) head, however, is the “workhorse” among elbow extensors and is active in all forms of extension.¹ It exhibits the earliest and the greatest electromyographic (EMG) activity.^{13, 20} The position of the elbow changes the effectiveness of the triceps brachii muscle. The triceps brachii muscle produces maximum torque with the elbow flexed to 90°. ²¹ But the position of the forearm does not change triceps brachii muscle activation, due to its attachment on the ulna and not on the radius. The triceps brachii muscle acts concentrically to perform elbow extension during a push-up and works eccentrically in a reverse action, controlling elbow flexion during the lowering phase of the push-up. Two studies investigated the muscle activation patterns of the three heads of the triceps brachii muscle to determine load sharing of the muscles during elbow movement.^{18, 22} Considerable differences were present between subjects in both studies indicating that there is not a consistent load-sharing pattern for activation of the triceps brachii muscle during elbow movement.

Only the activity of the long head of the triceps brachii muscle is altered by shoulder position because it crosses both the shoulder and the elbow joints. With the shoulder joint in extension and the muscle in a shortened position, the long head of the triceps brachii muscle cannot produce as much torque at the elbow. The long head also extends the arm at the shoulder and acts to adduct the arm, pulling the humerus back to the anatomic position from an elevated shoulder position.^{2, 13, 15–17, 23} During stimulation of the long head, adduction appeared to be the dominant action.¹⁴ The long head of the triceps brachii

muscle is most active during shoulder extension in ranges from 80° to 120° of shoulder flexion, and elbow flexion has little effect on muscle activation of the long head at the shoulder joint.²³

The long head of the triceps brachii muscle also produces arthrokinematic forces at the glenohumeral joint. It mitigates inferior translation of the humeral head when downward forces are transmitted through the joint. It also pulls the head of the humerus superiorly. The scapular attachment of the long head of the triceps brachii muscle influences actions at the glenohumeral joint. Older electrical stimulation studies¹⁴ demonstrated that the activation of the long head of the triceps brachii muscle alone, with the arm hanging down at the side of the body, elevated the head of the humerus toward the acromion. Stimulation with the arm abducted to 90° forced the head of the humerus into the glenoid cavity. The long head of the triceps brachii, the pectoralis major, and latissimus dorsi muscles all strongly adduct the arm, but the long head of the triceps brachii muscle counteracts the strong tendency of the other two muscles to pull the head of the humerus downward out of the glenoid fossa.¹⁴ Stimulation of the long head of the triceps brachii muscle suggests that adduction of the arm at the glenohumeral joint is achieved by drawing the humerus to the scapula without rotating the scapula, whereas stimulating the teres major muscle tended to draw the inferior angle of the scapula toward the humerus without moving the arm.¹⁴ These differences in function are not surprising because these two muscles have reverse long and short lever arms resulting in different moments of force at the glenohumeral joint.

Myers et al²⁴ investigated EMG activity using maximal volitional contraction (MVC) in the shoulder and the upper extremity muscles during 12 rubber-tubing exercises commonly used for shoulder rehabilitation. They found maximum activation of the triceps brachii muscle (67% MVC) during shoulder extension from 90° of shoulder flexion to a neutral position. They also found moderate activation during acceleration and deceleration while throwing, external and internal rotation at 0° shoulder abduction, scapular punches, middle and low scapular rows, and during shoulder flexion.²⁴

Bilateral triceps brachii muscles were monitored electromyographically with surface electrodes during 13 sports activities including overhand and underhand throws, tennis, golf, baseball batting, and one-foot jumps. Most of the records showed briefer, more intense contraction of the dominant triceps brachii muscle than the nondominant muscle. The more prolonged activity of the nondominant triceps brachii muscle appeared to function in counterbalance. Two outstanding exceptions were batting a baseball and golf swings, in which the nondominant triceps brachii muscle acted as a prime mover.²⁵ There is also a relationship between triceps brachii muscle activation and the velocity of the forehand drive in tennis. Increasing the velocity of a tennis swing causes earlier activation of the muscle. The muscle may activate earlier to provide stabilization to the elbow at impact and to prepare for the increased deceleration force needed during a follow through.^{26–28}

EMG analysis of muscle activation patterns during the crawl swimming stroke have been studied extensively over the past 50 years.²⁹ Rouard et al³⁰ concluded that the triceps brachii and biceps brachii muscles served antagonistic roles during the crawl stroke to

stabilize the elbow joint to improve the performance of the prime movers. Lauer et al³¹ found the greatest coactivation to be during early pull through to stabilize the elbow joint. Both investigators^{30,31} found the triceps brachii muscle to have approximately 40% MVC during mid-to-late pull through, having a large function in propulsion, and the least activity (15% MVC) during early recovery.

In an EMG analysis of the shoulder and the upper extremity muscles in five conditions comparing professional javelin throwers with a control group found that the triceps brachii muscle is moderately active during pulling, starting with the shoulder in 45° flexion and elbow fully extended, and with pushing, starting with the shoulder in neutral and the elbow flexed to 90° (40–51% MVC). With shoulder elevation, they found the triceps brachii muscle to be moderately active in the control group (47% MVC) and minimally active in the professional athletes (29% MVC) in the plane of the scapula to 140° elevation. During a goal-oriented slow throw, the triceps brachii muscle was moderately active in both the groups (53% MVC) and during a quick throw the biceps brachii muscle was maximally active in both the groups (98% MVC). The professional throwers achieved peak activation much sooner in the motion, but it was not statistically significant.³²

Conte et al³³ investigated EMG activity of the upper extremity, shoulder, and trunk muscles in two different conditions while utilizing a laptop, a touch pad, and an external mouse. They found greater activity in the triceps brachii and biceps brachii muscles while utilizing the touch pad against the external mouse. They believe the touch pad requires a greater degree of movement accuracy and, therefore, stabilization than the external mouse. They conclude that using an external mouse should be preferred to a touch pad by frequent users of a laptop to decrease muscle overload.

EMG analysis of the upper extremity muscles during driving^{34,35} demonstrates that the triceps brachii muscle is moderately active during turning to the same side the wheel was turning. Also, driving positions with the arm outstretched produced greater muscular activity than a driving position with the arms closer to the body in a more vertical position.

Anconeus

The anconeus muscle assists the triceps brachii muscle in extension at the elbow joint.¹³ The muscle contributes approximately 15% of the extension movement at low torque levels.¹⁹ As elbow flexion increases, the activity of the anconeus decreases, and at greater than 45° of elbow flexion, the anconeus muscle becomes a lateral stabilizer of the humeroulnar joint.³⁶ Its adherence to the lateral humeroulnar capsule allows it to actively stabilize the elbow, preventing posterolateral dislocation and providing an active constraint to protect the passive lateral collateral ligament and joint capsule.⁶ This role as a stabilizer has also been confirmed electromyographically. The medial head of the triceps brachii, anconeus, and supinator muscles work together to stabilize the elbow joint during pronation and supination of the forearm by abducting the ulna.^{13,37} The anconeus muscle is also active during all index finger movements and during maximal gripping.^{38, 39} During gripping, the anconeus muscle may be activated to stabilize the elbow and counteract the

elbow flexion moment caused by forceful activation of the wrist flexor muscles.⁴⁰

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that it crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 32-1 grossly represents the functional unit of the triceps brachii muscle.⁴¹

Box 32-1 Functional unit of the triceps brachii/anconeus muscles

Action	Synergists	Antagonist
Elbow extension	Triceps brachii Anconeus	Biceps brachii Brachioradialis Brachialis Pronator teres

The long head of the triceps brachii muscle is synergistic with the latissimus dorsi, teres major, and teres minor muscles, which can all act as adductors and extensors of the arm at the shoulder joint. The long head of the triceps brachii muscle works synergistically with the coracobrachialis, the short head of the biceps brachii, the clavicular head of the pectoralis major, and the deltoid muscles to pull the humerus superiorly and also to eccentrically control inferior translation of the humerus. The subscapularis and costal portion of the pectoralis major muscle provide a stabilizing antagonistic pull.²

The deltoid and supraspinatus muscles are antagonistic to shoulder adduction and the pectoralis major, anterior deltoid, and coracobrachialis muscles are antagonistic to shoulder extension.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Triceps Brachii

Trigger points in the triceps brachii muscle occur frequently and can be found in any of the three heads of the muscle. They are most commonly found in the long head and the lateral portion of the medial head of the muscle. The referral patterns for each portion of the

muscle vary and can refer pain to the posterior or anterior portions of the upper arm and elbow. In this muscle, it is important to distinguish TrPs in the distal portion of the muscle from attachment enthesopathy of the common triceps brachii tendon.

Long Head

Trigger points in the long head of the triceps brachii muscle (Figure 32-3A, left) refer pain and tenderness upward over the posterior arm to the back of the shoulder, occasionally to the base of the neck in the region of the upper trapezius muscle, and sometimes down the dorsum of the forearm, skipping the elbow. Trigger points are often located in the central portion of the long head muscle belly.

Figure 32-3. Referred pain patterns (dark red) from TrPs in the triceps brachii muscle (medium red). A, Trigger points in the left long head and in the lateral portion of the right medial (deep) head. B, Trigger points in the left lateral head and deep in the right medial head under the tendon in the musculotendinous attachment region. C, Additional pain referral pattern for TrPs in the right medial (deep) head of the triceps brachii muscle.

Medial Head

The medial head of the triceps brachii muscle may have TrPs that lie mid-fiber in the lateral portion (Figure 32-3A, right) or in the deeper segment of the medial portion of the muscle (Figure 32-3C). Trigger points in the lateral portion of the medial head presents with referred pain to the lateral epicondyle and are often a common component of the epicondylalgia more commonly known as “tennis elbow” (Figure 32-3B, right). Pain may also extend to the radial aspect of the forearm (Figure 32-3A, right). If the deep portion of the medial head is involved, pain and tenderness is present over the medial epicondyle and may extend to the volar surface of the fourth and fifth digits and occasionally into the adjacent palm and the middle finger (Figure 32-3C). Pain may also occur along the inner

side of the forearm from these TrPs at this location.⁴²

Lateral Head

Pain and tenderness from TrPs in the lateral head of the triceps brachii muscle (Figure 32-3B, left) refer over the arm posteriorly, sometimes to the dorsum of the forearm, and occasionally to the fourth and fifth digits. Taut bands in the lateral head may cause entrapment of the radial nerve.

Distal Triceps Brachii

Trigger points in the distal portion (Figure 32-3B, right) of the triceps brachii muscle cause local tenderness over the olecranon process. Trigger points in this region typically occur secondarily to TrPs in the long head, lateral head, and deep portion of the medial head of the triceps brachii muscle.

Anconeus

A TrP in the anconeus muscle refers pain and tenderness locally to the lateral epicondyle (Figure 32-4) and is often involved in cases of lateral epicondylalgia and chronic “tennis elbow” that persist after TrPs in the wrist extensor and triceps brachii muscles have been inactivated.

Figure 32-4. Anconeus muscle pain referral pattern (dark red) for TrPs located within the muscle (light red).

3.2. Symptoms

Patients who have TrPs in the triceps brachii muscle often report pain that is vague and hard to localize in the back of the shoulder and the upper arm. In highly irritable cases, the patient may report pain in the dorsal and volar aspect of the forearm and into the fourth and fifth digits of the hand. They may also report pain localized at the medial or lateral aspect of the elbow joint and often present with symptoms similar to “tennis elbow” or “golfer’s elbow.” Patients do not typically report restricted motion though they may be unaware of any elbow or forearm joint restriction because of the automatic tendency to keep the elbow slightly flexed and out of the painful range. They may compensate for the slightly reduced reach by additional shoulder blade or trunk movements. Because of

tenderness referred to the inner elbow, the elbow may be held away from the side to avoid body contact and the patient may be unable to place their elbow on a supporting surface. Patients may report that they cannot place the elbow on the center console or arm rest while driving or performing computer work secondary to pain.

The patient may also report pain during activities that require forceful extension of the elbow such as playing tennis (dominant arm), playing golf (nondominant arm), or while swimming (crawl stroke). Pain from TrPs in the lateral head of the triceps brachii muscle can play an important role in the pain experience and loss of function of patients diagnosed with lateral epicondylalgia or “tennis elbow” (see Chapter 41).

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the patient’s progress as symptoms improve or change. For proper examination of the triceps brachii and anconeus muscles, the clinician should assess the patient’s upper extremity and shoulder girdle posture while standing with arms at the side, elbow carrying position, active and passive ranges of motion of the upper extremity joints, muscle activation patterns in the shoulder girdle, and scapulohumeral rhythm. To identify TrPs in the triceps brachii muscle that may be limiting the range of motion and thus influencing dysfunction, the clinician should identify the limited range of motion by performing a specific range of motion testing for all parts of the triceps brachii muscle. The long head of the triceps brachii muscle crosses both the elbow and shoulder joints and therefore shoulder position should be considered while evaluating this portion of the triceps brachii muscle. By increasing muscle tension, TrPs can produce biomechanical dysfunction.

Bron et al⁴³ assessed the prevalence of muscles with TrPs in 72 patients with chronic nontraumatic unilateral shoulder pain. They found the highest prevalence of muscles with TrPs in the infraspinatus (93%) and upper trapezius (94%) muscles. They also found that 56% of the patients had TrPs in the triceps brachii muscle, though they did not report the specific prevalence of TrPs in the three different heads of the triceps brachii muscle.

Muscle-specific resisted testing should be carried out to identify impairments in muscle function and reproduction of painful symptoms with loading. Weakness or inhibition of the triceps brachii muscle can be identified by resisting elbow extension in 90° of elbow flexion. Resisting shoulder extension (between 80° and 120° of shoulder flexion) with the elbow straight maximally activates the long head of the muscle and helps differentiate it from the medial and lateral heads. The forearm position does not affect triceps brachii muscle activation patterns due to its attachment on the ulna.²³ To differentiate the activation of the anconeus muscle, resistance to elbow extension should be applied with the elbow in less than 45° of flexion or resistance can be applied at the end range of forearm

Accessory joint motion of the elbow and shoulder joints (including the acromioclavicular and sternoclavicular joints) should be manually tested to determine if

faulty arthrokinematics are a contributing factor to triceps brachii TrPs. If the shoulder girdle is found to be a contributing factor to activation and perpetuation of TrPs in the triceps brachii muscle, effective joint movement should be restored.

If a humeral epicondyle is painful due to TrPs, it may also be sensitive to tapping or vibration because of referred tenderness. Pain in the lateral epicondyle due to triceps brachii TrPs often persists in patients diagnosed with “tennis elbow” after the supinator, biceps brachii, and brachioradialis TrPs have been inactivated. Residual percussion tenderness of the posterior aspect of the epicondyle indicates that triceps brachii TrPs are likely referring pain to this area.

3.4. Trigger Point Examination

The patient is positioned supine or prone to gain access to the triceps brachii and anconeus muscles. Cross-fiber pincer palpation can be utilized to identify TrPs in the long head of the triceps brachii muscle and cross-fiber flat palpation technique can be used to identify TrPs in the medial and lateral heads of the triceps brachii muscle and in the anconeus muscle.

Triceps Brachii

Long Head

Trigger points in the long head of the triceps brachii muscle are typically found deep in the midportion of the muscle, a few centimeters distal to where the long head of the triceps brachii muscle crosses the teres major muscle. Cross-fiber pincer palpation is usually necessary to locate TrPs in this muscle. The fingers should encircle the triceps brachii muscle (Figure 32-5A), reaching in until they encounter the humerus. The long head of the triceps brachii muscle can be separated slightly from the humerus and its fibers can be rolled between the digits. Clusters of TrPs are often present and are identified by their multiple taut bands, by reproduction of the patient’s pain, and often by local twitch responses. The taut bands associated with TrPs in the long head of the triceps brachii muscle are likely to contribute to the tenderness of TrPs near the musculotendinous junction.

Figure 32-5. Trigger point examination of the triceps brachii muscle. A, Cross-fiber pincer palpation to identify TrPs in the long head of the right triceps brachii muscle. B, Cross-fiber flat palpation to identify TrPs in the lateral portion of the medial head. C, Cross-fiber flat palpation to identify TrPs in the medial portion of the medial head. D, Cross-fiber flat palpation to identify TrPs in the lateral head. E, Cross-fiber flat palpation to identify TrPs in the distal portion of the muscle, where all three heads conjoin.

Medial Head

Trigger points in the lateral portion of the medial head are found with cross-fiber flat palpation (Figure 32-5B). Trigger points can also be found deep in the medial border of the mid-fiber region of the medial head, just above the medial epicondyle. Trigger points here are found by cross-fiber flat palpation with the patient lying supine and the arm externally rotated at the shoulder joint to expose the muscle belly (Figure 32-5C).

Lateral Head

Trigger points in the lateral head of the triceps brachii muscle can be identified by a cross-fiber flat palpation at the mid-belly in the lateral border of the lateral head, just above the point where the radial nerve exits from the radial groove (Figure 32-5D). The taut bands of TrPs in this part of the muscle may entrap the sensory fibers of the radial nerve as it passes through this area. In this case, firm palpation along the lateral intermuscular septum, in the region where the radial nerve penetrates the septum, is likely to cause a tingling sensation in the hand.

Distal Triceps Brachii

Trigger points that are present near the tendon insertion of the triceps brachii muscle are

found deep in the distal medial head with a cross-fiber flat palpation near the area of fusion of the three heads, just above the olecranon, to which it refers pain (Figure 32-5E).

Anconeus

Although the muscle is thin, TrPs in the anconeus muscle are deep and can be palpated using cross-fiber flat palpation lateral and inferior to the olecranon with the elbow slightly flexed and supported (Figure 32-6).

Figure 32-6. Trigger Point examination of the anconeus muscle using cross-fiber palpation.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the triceps brachii muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁴⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position(s) for an extended period of time.

Activation of TrPs in the triceps brachii muscle may occur due to repetitive overload from overuse of forearm or axillary crutches, the stress of using a cane that is too long, short upper arms, excessive city driving in a car with manual transmission requiring extensive and repetitive manual gear shifting, or from any strong repetitive pushing action. Formation of TrPs may also occur due to traumatic overuse such as a catching the weight of the body during a fall on an outstretched hand. Investigators found that the triceps brachii muscle achieved peak %MVC prior to the time of peak impact force during three different fall

scenarios from two different heights.⁴⁵ Activities such as tennis or overenthusiastic conditioning exercises (golf practice or push-ups) may also perpetuate TrPs in the triceps brachii muscle. Interestingly, the TrPs in the long head of the triceps brachii muscle are also likely to be activated by sitting for long periods with the elbow held forward in front of the plane of the chest or abdomen without proper elbow support (eg, driving a car on a long trip, or other handwork without elbow support).

Triceps brachii TrPs were activated by jackknife positioning of a patient during nephrolithotomy in a way that held the muscle in the stretched position for a prolonged period of time.⁴⁶ The TrPs were inactivated by deep massage of the TrPs and passive stretch, and the patient was relieved of the previously enigmatic pain.

Pain alters muscle activation patterns and this can also cause TrP formation. Investigators have induced pain in the triceps brachii and biceps brachii muscles with repetitive dynamic reaching, and the muscle activation patterns of the muscles in the upper arm changed.⁴⁷ When pain was induced, the activity of the biceps brachii and brachioradialis muscles decreased, but the activity in the triceps brachii muscle increased. A decreased activity in the biceps brachii muscle was compensated for by an increased activity in the other flexor muscles. In extension, compensation for decreased triceps brachii muscle activity is not possible, therefore the muscle should continue to act to complete the task at the same speed. The lack of redundancy of muscles in the posterior arm to perform extension motion may predispose the triceps brachii muscle to injury and TrP formation, especially from repetitive overuse because the muscle should continue to function to complete dynamic tasks despite pain and injury.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.⁴⁸ Therefore, musculature in the referred pain areas for each muscle should also be evaluated. Release of the TrP in the associated muscle often allows for an immediate decrease in the pressure pain threshold of the associated TrPs.⁴⁷

When a TrP is identified in the long head of the triceps brachii muscle, one should also examine the posterior deltoid, latissimus dorsi, teres major, and teres minor muscles for associated TrPs.

When elbow pain persists in the lateral epicondylar area after eliminating TrPs in the medial head of the triceps brachii muscle, the anconeus, supinator, brachioradialis, and extensor carpi radialis longus muscles should be examined for associated TrPs.

Trigger points in the ipsilateral latissimus dorsi, serratus posterior superior,⁴⁹ coracobrachialis, or subscapularis muscles may cause associated TrPs in the triceps brachii muscle. For lasting release of the triceps brachii TrPs, TrPs in these other muscles should be inactivated.

As antagonists to the triceps brachii muscle are part of the functional unit, the biceps brachii and brachialis muscles are prone to develop TrPs (often latent) during chronic TrP involvement of the triceps brachii muscle.

4.3. Associated Pathology

Because pain from the triceps brachii muscle may concentrate on the back of the arm and extend into the hand, it is sometimes erroneously thought to result from C7 radicular pain.⁵⁰

Whenever the patient reports lateral or medial elbow pain, and diagnoses of “tennis elbow,” “golfers elbow,” lateral or medial epicondylitis, olecranon bursitis, or thoracic outlet syndrome are being considered; evaluation for TrPs in the triceps brachii muscle should also be performed. Tennis elbow (lateral epicondylitis) is discussed in detail in Chapter 41 and thoracic outlet syndrome in Chapter 33. Special tests for lateral epicondylitis in most cases are negative, but the patient reports pain in the area of the lateral epicondyle. Careful palpation of the triceps brachii and anconeus muscles may reveal that TrPs in this area have been causing referred pain to the epicondyle. The same is true of special tests for thoracic outlet syndrome, except for the Roos’ test, which may reproduce the patient’s pain due to prolonged use of the triceps brachii muscle to stabilize the arm in the testing position.

Pain referred from the triceps brachii muscle to the vicinity of the elbow joint may be mistakenly attributed to arthritis.⁵⁰ Osteoarthritic changes in the joint may also be associated with locking or grinding and the range of motion limitations may be evident in both flexion and extension. With triceps brachii TrPs, a passive range of motion is limited to flexion only, if at all.

Cubital tunnel syndrome is more likely to cause hypoesthesia of the skin in the ulnar distribution of the hand and weakness and clumsiness of the hand, rather than pain.⁵¹ This syndrome is associated with slowing of ulnar nerve conduction through the cubital tunnel, whereas the pain from triceps brachii TrPs is not.

Lateral elbow pain that may mimic referred pain from TrPs in the lateral portion of the medial head of the triceps brachii muscle may also be caused by entrapment of the motor branch of the radial nerve, the posterior interosseous nerve, by the arcade of Frohse, or other soft tissues overlying the head of the radius. This nerve pathology is primarily characterized by functional deficits at the wrist, atypical of triceps brachii TrPs.⁵²

Entrapment of the radial and ulnar nerves may occur from TrPs in the lateral head of the triceps brachii muscle or from the presence of an anomalous anconeus epitrochlearis muscle, respectively. Nerve compression by these muscles can cause neurologic symptoms such as dysesthesias and loss of motor control in the forearm and hand.

Trigger points in the lateral border of the lateral head of the triceps brachii muscle (Figure 32-3B, left), just proximal to the exit of the radial nerve from the musculospiral (radial) groove (Figure 32-2), are often associated with sensory signs and symptoms of compression of the radial nerve. The patient commonly reports tingling and numbness (dysesthesias) over the dorsum of the lower forearm, wrist, and hand to the base of the middle finger, which lies in the sensory distribution of the radial nerve. By comparison, the pain from TrPs in the lateral head of the triceps brachii muscle appears in the two “ulnar” digits (fourth and fifth) and typically aches in nature. Symptoms of nerve compression may

be relieved within minutes to days after the release of the TrP that eliminates the responsible taut band of the muscle. An injection of a local anesthetic solution into the TrP may also temporarily block the radial nerve.

Radial nerve entrapment can also occur beneath the triceps brachii muscle. Careful postmortem dissection revealed an accessory band of the lateral head of the triceps brachii muscle originating below the spiral groove in almost every cadaver studied. The attachment of this slip of muscle to the humerus forms a fibrotic arch of variable tightness over the radial nerve. This arch is distinct from the opening of the lateral intermuscular septum.⁵³ A patient with a 3-year history of an atraumatic radial paresis progressing to a paralysis was relieved by surgical release of the fibers of the lateral head of the triceps brachii muscle that attached near the radial nerve.⁵⁴ The taut fibers caused by TrPs in this portion of the muscle may tense this arch, contributing to a nerve entrapment.

The anconeus epitrochlearis muscle is an anomalous muscle that attaches from the inferior surface of the medial epicondyle to the medial olecranon.⁶ It overlies the ulnar nerve and becomes taut in flexion, potentially causing compression at the cubital tunnel. The presence of the muscle has been confirmed by multiple cadaveric studies, and its incidence in the general population has been estimated between 4% and 34%.^{7,55,56} Compression of the ulnar nerve by an edematous or hypertrophied anconeus epitrochlearis muscle can cause compression of the nerve, and it has been identified as such in several studies.^{7,55,57-63} Pain from compression by the anconeus epitrochlearis muscle often presents as medial elbow pain that does not respond well to conservative treatment. Surgical release of the muscle is often recommended for relief of symptoms. It has been postulated that the anconeus epitrochlearis muscle may be a cause of unrelenting medial elbow pain in overhead athletes.⁶⁴ Compression of the ulnar nerve by the anconeus epitrochlearis muscle was identified as the cause of medial elbow pain in three baseball pitchers.⁵⁴ Surgical release of the muscle was performed for all and each was able to return to their prior level of play.

5. CORRECTIVE ACTIONS

The patient should avoid habitual, sustained, or repetitive motions that overload the triceps brachii muscle, including activities that require excessive pushing or sustained positions with the elbows straight and the arms held away from the body. Postural adjustments when typing, writing, and reading should be made to keep the arm vertical with the elbow behind the plane of the chest and not projected forward. Whenever possible, an armrest of suitable height should support the elbow. To correct for short upper arms in relation to the torso height, a chair with adjustable armrests is recommended. The height of the armrests should always be adjusted properly to support the arms when seated (see Figure 6-9).

The patient should avoid sleeping postures that tightly flex the elbow or extend the shoulder (elbow falling behind the body). To assist in avoiding these positions, the patient can wrap a small towel loosely around the elbow to avoid bending it past 90° (see Figure 30-6) and place a pillow under the arm while lying supine so that the shoulder is maintained in a neutral position.

Sporting activities and exercises should also be addressed. In tennis, the patient may change to a lighter-weight racquet. Also, it may be helpful to shorten the grip on the racquet handle or “choke up,” which reduces the leverage on the triceps brachii muscle. When training to increase the velocity of a swing, the progression should be done in a gradual manner to decrease traumatic overload of the triceps brachii muscle.²⁸ Pull-ups, push-ups, bench press, and military press, which easily overload the arm muscles, should be avoided until after recovery and then resumed gradually.

Trigger point self-pressure release techniques can also be helpful in resolving pain from triceps brachii TrPs. The patient may inactivate TrPs in the long head of the triceps brachii muscle by firmly grasping and holding the muscle belly with the elbow in slight flexion and the upper extremity supported (Figure 32-7A) or by resting the affected hand on the opposite shoulder (Figure 32-7B). Massage to the tender area may be more tolerable if pain with the above technique is too intense. Pressure applied with the flat aspect of the thumb can be utilized to release TrPs in the medial head (Figure 32-7C), and finger pressure or a tennis ball can be utilized to release TrPs in the lateral head (Figure 32-7D).

Figure 32-7. Self-pressure release of TrPs. A, Long head of triceps brachii muscle with arm supported. B, Long head of triceps brachii muscle. C, Medial head. D, Lateral head with tennis ball.

Trigger point compression alone has been found to be effective in treating chronic shoulder complaints. Pressure should be mildly painful but tolerable and can be applied for bouts as short as 15 seconds in duration to be effective.⁶⁵ Following treatment for

inactivation of TrPs in the triceps brachii muscle, the patient should passively and gently stretch the entire muscle daily (Figure 32-8).

Figure 32-8. Self-stretch of the triceps brachii muscle.

Clinical Considerations of Upper Back Shoulder and Arm Pain

César Fernández de las Peñas and José L. Arias-Buría

1. CERVICAL RADICULAR PAIN

1.1. Overview

The presence of symptoms in the upper extremity is usually associated with the presence of nerve entrapment or radicular pain. However, once any nerve involvement is excluded, clinicians should consider the presence of TrPs in the musculature for which referred pain could mimic this condition, for example, the infraspinatus or scalene muscles.

Cervical radiculopathy is defined as an abnormality of a nerve root with an origin in the cervical spine.¹ Cervical radiculopathy has a prevalence ranging¹ from 83.2 per 100 000 people to 3.3 cases per, 1 000,² affecting men more frequently than women. It has a peak annual incidence of 2.1 cases per 1 000 and it occurs most commonly in the fourth and fifth decades of life.³ The seventh (60%) and the sixth (25%) cervical nerve roots are the most commonly affected.⁴ Cervical radiculopathy is caused by a cascade of events that lead to nerve root distortion, intraneural edema, impaired circulation and focal nerve ischemia, localized inflammatory response, and altered nerve conduction. The localized inflammatory response of the nerve is stimulated by chemical mediators in the disk that may incite the production of inflammatory cytokines, substance P, bradykinin, tumor necrosis factor α , and prostaglandins.⁵

The most common compressive causes of cervical radiculopathy include disk herniation and degenerative spine components such as osteophytes, facet joint hypertrophy, and ligament hypertrophy. Disk herniation causes occur when nuclear material from the acute soft disk herniation impinges on a nerve root; whereas the degenerative causes are associated with a loss of disk height and a “hard disk” bulging with resultant compressive elements such as the ligaments and osteophytes.⁵

1.2. Initial Evaluation of a Patient with Cervical Radicular Pain

In patients with cervical radicular pain, the neurologic symptoms may lead to pain, motor weakness, and/or sensory deficits along the affected nerve root.⁵ Depending on the nerve root affected, symptoms may exist concurrently in the neck, shoulder, upper arm, or forearm.¹ Often, pain and sensory changes are not consistent and may result in a dull ache to a severe burning pain in the neck and upper extremity. Pain is typically noted in the medial border of the scapula and shoulder that can progress down the ipsilateral arm and hand along the sensory distribution of the involved nerve root.⁶ Clinicians should disregard the muscle involvement because the referred pain elicited by TrPs in some muscles can be similar to the dermatomal patterns of spinal nerve roots.⁷

Motor weakness associated with radiculopathy may provide a variety of clinical scenarios and is associated with specific nerve root levels.¹ Specific nerve root weakness typically presents in the following patterns: scapular weakness with C4; shoulder abduction or elbow flexion weakness with C5; wrist extension/supination with C6; triceps brachii, wrist flexion/pronation with C7; and finger flexor/interossei with C8.⁸ Muscle weakness should be complemented with examination of deep tendon reflexes because TrPs can also be responsible for muscle weakness. In fact, cervical radicular pain typically presents with diminished deep tendon reflexes (muscle stretch reflex). Loss of deep tendon reflexes is usually said to be the most reliable clinical finding and has been noted in 70% of the cases.⁸ Generally, the decline in reflexes follows a predictable radicular pattern.

Sensibility changes (sensation variations) of the affected nerve roots may help localize the level of the lesion. C4 nerve root distribution tends to affect the shoulder and upper arm; C5 nerve root distribution the lateral aspect of the arm; C6 nerve root affects the lateral aspect of the forearm, hand, and thumb; the C7 nerve root the dorsal lateral forearm and third digit; and the C8 nerve root the medial forearm, hand, and fourth and fifth digits.⁹ It is important to consider that referred pain areas from TrPs may also exhibit sensory changes, so it is important to complement neurologic examination with musculoskeletal assessment.

Patients with cervical radicular pain often hold their head away from the injurious side, avoiding rotation to the affected side.⁶ Cervical range of motion is typically decreased, specifically rotation to the affected side² and also extension. Clinicians should take into account that cervical spine movement should reproduce radicular pain symptoms in these patients. The Spurling's test is one of the most common clinical tests used for assessment of cervical radicular pain. This test combines cervical lateral flexion and compression and is considered positive if symptoms of radicular pain are reproduced or worsen during the compression.⁸ Other authors have proposed the Upper Limb Tension Test (ULTT) as a good screening test for ruling out cervical radicular pain. Wainner et al² developed a clinical prediction rule for diagnosis of cervical radicular pain: positive Spurling's test, cervical rotation range of motion <60°, positive cervical distraction test, and positive ULTT. When all four tests are positive, the specificity was 99% with an LR+ of 30.0.²

1.3. Trigger Points and Cervical Radiculopathy

The presence of cervical radicular pain and symptoms does not exclude a potential relevance of TrPs. In fact, some patients with symptoms in the upper extremity are mistakenly diagnosed as having cervical radicular pain when the problem is entirely TrPs. In patients with real cervical radiculopathy, TrPs can be a worsening musculoskeletal factor for their symptoms. In addition, patients with cervical radicular pain reported a higher number of tender spots on the side of the radiculopathy, with predilection toward muscles innervated by the involved nerve root.¹⁰ Hsueh et al¹¹ observed that C3-C4 lesions were associated with levator scapulae and latissimus dorsi TrPs; C4-C5 lesions with splenius capitis, levator scapulae, and rhomboid minor TrPs; C5-C6 lesions with splenius capitis, deltoid, levator scapulae, infraspinatus, upper paraspinal, and latissimus dorsi TrPs; and C6-C7 lesions with latissimus dorsi and rhomboid minor TrPs. Sari et al¹² described the presence of active TrPs in the upper trapezius, multifidus, splenius capitis, levator scapulae, rhomboids, and deep paraspinal muscles in individuals with cervical radiculopathy. These authors hypothesized that in patients with nerve involvement, the cervical root compression can be considered a precipitating factor for the development of active TrPs in the associated muscles.¹² This finding has been also observed in individuals with lumbosacral radicular symptoms who reported the presence of TrPs in the gluteal muscles.¹³ Proper identification of TrPs in patients with radicular pain can be crucial because lack of treatment of TrPs could lead to further aggravation of the symptoms in these patients. In fact, a recent study found that injection of TrPs in the affected muscles in patients with radicular pain was effective for decreasing pain.¹⁴

However, these studies examined muscles showing a segmental relationship with the affected radicular segment but did not include examination of other muscles that referred pain may mimic cervical radicular pain. For instance, active TrPs in the scalene, infraspinatus, supraspinatus, teres minor, latissimus dorsi, or pectoralis minor muscles can refer to the upper extremity, mimicking symptoms consistent with radicular pain diagnosis. In an older report, Escobar and Ballesteros¹⁵ described four case reports where active TrPs in the teres minor muscle mimic ulnar neuropathy or C8 radiculopathy symptoms. More recently, Qerama et al¹⁶ found the presence of active TrPs in the infraspinatus muscle in individuals with symptoms compatible with carpal tunnel syndrome but normal nerve conduction study. In this study, approximately two-thirds of patients referred with a clinical suspicion of carpal tunnel syndrome, but normal nerve conduction studies, exhibited active TrPs in the infraspinatus muscle.¹⁶

2. THORACIC OUTLET SYNDROME

2.1. Overview

Thoracic outlet syndrome (TOS) is a broad term used to describe upper extremity symptoms, and it is usually defined as “compression of the brachial plexus and subclavian

artery by attached muscles in the region of the first rib and clavicle,” which highlights the structures usually considered involved. The anatomic relation of these structures is illustrated in Figure 20-9 (from which a portion of the clavicle has been removed). Both the brachial plexus and the subclavian artery emerge through the interscalene triangle bounded by the anterior and middle scalene muscles and the first rib, where nerves of the brachial plexus and the subclavian artery pass over the first (or, rarely, the cervical) rib. The subclavian vein, accompanied by a lymphatic duct, passes over the first rib anteriorly (medially) to the attachment of the anterior scalene muscle. Entrapment symptoms may be of neural, vascular, and/or lymphatic origin. The lower trunk of the brachial plexus is formed from spinal nerves C8 and T1. The T1 nerve exits the spinal foramen between the first and second thoracic vertebrae, and courses cephalad to hook over the first rib where its fibers, and those of the C8 spinal nerve, are wedged between the subclavian artery and the rib attachment of the middle scalene muscle.

Symptoms experienced by these patients are related to compression or tension of the brachial plexus and the subclavian artery and vein in an area located above the first rib and behind the clavicle. The scalenus anterior muscle, the scalenus medius muscle, and the first rib define borders of the thoracic outlet. Pathology or dysfunction of these structures as well as that of the clavicle, a cervical rib or transverse process of C7, pectoralis minor, omohyoid, subclavius, and scalene minimus muscles are associated with TOS. In their course from the interscalene triangle to the axilla, these neurovasculature structures are covered with a fascial sheath (part of the deep cervical fascia), which can become problematic.¹⁷ Fibrous bands, both congenital and acquired, also restrict movements of the clavicle and first rib. The term TOS does not specify the compressing agent and does not identify the structure being compressed.

The thoracic outlet region includes three major areas in which the compression can occur: interscalene triangle, costoclavicular space, and subpectoralis minor space. Other causes include congenital bony structures (eg, cervical rib), fibromuscular anomalies, postural deviations, and muscle imbalance.

Entrapment at the Interscalene Triangle

Because the brachial plexus runs between the scalenus anterior and medius muscles, increased tension from either muscle can be responsible for the entrapment of neurovascular structures in the interscalene triangle causing potential symptoms. The reason for this increased muscle tension remains enigmatic in the literature. One reason for an increased muscle tone in the scalene muscles may be the presence of TrPs. In addition, the scalene muscles can hypertrophy with trauma or repetitive motion. Sanders¹⁸ found 25% increase in connective tissue in the scalene muscles following injury.

Thomas et al¹⁹ emphasized the middle scalene muscle as being just as important as the anterior scalene muscle in producing TOS. Because the middle scalene muscle is usually a larger, more powerful muscle and has leverage as good as, if not better than, the anterior muscle for elevating the first rib, the middle scalene muscle likely is more important. Of

108 patients who received operative care for TOS, 23% had an anterior insertion of the middle scalene muscle that placed the lower trunk of the brachial plexus and the subclavian artery in direct contact with the muscle's anterior margin. This relationship would make the nerves and artery more vulnerable to abnormal sustained tension of the middle scalene muscle caused by TrPs. In a study of 56 cadavers, the lower trunk of the brachial plexus rested on the inferior portion of the margin of the middle scalene muscle in practically all cases.¹⁹

Entrapment at the Costoclavicular Space/First Rib

The compression of the neurovascular bundle of the upper extremity between the clavicle and the first rib is denominated costoclavicular syndrome. Any muscle tightness that tends to elevate the first rib (ie, scalene muscle tightness) could aggravate this syndrome. In addition to the scalene muscles, increased tension of the pectoralis minor muscle can contribute indirectly to first rib elevation when the third through fifth ribs (sometimes also the first and second ribs) are upward.

Makhoul and Machleder²⁰ reviewed the surgical findings in patients who received operative care for costoclavicular syndrome and found numerous references to compression of the subclavian vein against the first rib because of enlargement of the subclavius muscle. An abnormality of the subclavius muscle was found in 19.5% of their 200 surgical cases, and an exostosis at the subclavius tubercle was observed in 15.5%, suggesting abnormally increased tension of that muscle. The subclavius muscle attaches laterally to the middle third of the clavicle and medially to the first rib and its cartilage at their junction.²¹ Prolonged shortening of this muscle, for instance, because of a rounded shoulder posture, could produce a force that would tend to elevate the rib.

Some authors emphasized the important relationship between the TOS and dislocation or subluxation of the first rib.^{22–24} The treatment, which the authors found to successfully restore normal relations of the first rib and relieve the patient's symptom, was essentially an isometric contract-relax technique specifically for the scalene muscles. This finding raises the question of whether the release of the first rib elevation is not primarily a matter of effectively inactivating scalene TrPs and releasing the abnormal tension in these muscles. Clinicians would expect that downward pressure, applied to the posterior portion of the first rib after the scalene tension is released, facilitates restoration of the normal anatomic relations at the costotransverse joint.

Entrapment at the Subpectoralis Minor Space

The subpectoralis minor space is located below the coracoid process and under the pectoralis minor muscle insertion. Kendall et al²⁵ defined coracoid pressure syndrome as “a condition of arm pain in which there is compression of the brachial plexus . . . [that] is associated with muscle imbalance and faulty postural alignment.” Shortening of the pectoralis minor muscle can lead to a narrowing of the subpectoralis minor space by increasing pressure on the blood vessels and brachial plexus. Forward depression of the

coracoid process tends to narrow the space available for the three cords of the brachial plexus, the axillary artery, and the axillary vein to pass between the attachment of the pectoralis minor muscle to the coracoid process and the rib cage. Some muscles demonstrate weakness because of the forward and downward tilting of the coracoid process (lower portion of the trapezius muscle), whereas others tend to be tight (pectoralis minor muscle). In fact, TrPs and their taut bands commonly shorten the pectoralis minor muscle and most likely contribute to this syndrome. The pull of tight pectorals can overstretch and weaken the lower trapezius muscle and this weakness can allow the scapula to ride upward and tilt forward, favoring adaptive shortening of the pectoralis minor muscle, creating a perpetuating cycle. Clinicians should consider that TrPs can also inhibit muscular activity, for example, in the lower portion of the trapezius muscle. Finally, a tight pectoralis minor muscle may also compress the neurovascular structures during hyperabduction of the shoulder. Wright termed this syndrome as hyperabduction syndrome.²⁶

Entrapment due to Congenital Abnormalities

The incidence of a cervical rib is less than 1% and may be bilateral. Among 40 000 consecutive chest x-ray examinations of army recruits, completely articulated cervical ribs were found in 0.17% and anomalous or deformed first ribs in 0.25%.²⁰ The cervical rib size varies from a bony exostosis to a full-grown cervical rib with ligamentous cartilaginous or bony attachment to the first rib. The female:male ratio is 2:1.¹⁷ When present, a cervical rib can intensify the symptoms that result from elevation of the rib by the scalene muscles because all structures crossing over a cervical rib are more sharply angulated than usual. In fact, a cervical rib causes the brachial plexus to be pulled against the scalene fascial bands and C8-T1 symptoms can develop. A cervical rib, in a patient exhibiting rounded shoulder and forward head posture, can cause pressure on both the plexus and the vessels.

A higher number of congenital anomalies can also increase the likelihood of entrapment at the thoracic outlet. A congenital abnormally narrow space between the attachments of the two scalene muscles at the first rib will restrict the opening and make the neurovascular structures more vulnerable to compression. An additional space-occupying structure, such as an accessory muscle or fibrous band that passes through the interscalene triangle, will have the same effect. Sharp fibrous edges of the scalene muscles or fibrous bands bordering or within the interscalene triangle can make components of the brachial plexus more vulnerable to compression as well. Makhoul and Machleder²⁰ analyzed 200 consecutive surgically treated cases of TOS for developmental anomalies and reviewed the literature. A congenital abnormality was found in 66% of cases, higher than that in unselected populations. A cervical rib or first rib abnormality appeared in 8.5% of cases. Supernumerary scalene muscles were found in 10%, developmental variations of scalene muscles in 43%, and variations of the subclavius muscle in 19.5%. However, the only correlation between the clinical and the morphologic characteristics was thrombosis of the subclavian vein due to enlargement of the subclavius muscle system.

2.2. Initial Evaluation of a Patient with Thoracic Outlet Syndrome

The history and physical examination have proved to be the most useful for making the diagnosis of TOS. Further testing may help confirm that there is entrapment and may indicate where it is, but usually tells the clinician little about what is causing the entrapment, which is what a surgeon needs to know. The exception to this is venous entrapment, implicating the subclavius muscle. Physical signs may reflect entrapment of the brachial plexus, subclavian artery, subclavian vein, or the lymph duct from the arm. Electrodiagnostic procedures test for compromise of nerve function, and provocative maneuvers are commonly used to detect both arterial and nerve involvement. Neural involvement is reported to be much more common than arterial involvement,²⁰ and the literature rarely mentions venous/lymphatic compromise except in connection with the costoclavicular syndrome.

Patients typically report pain in the subscapular, scapular, cervical, and cervicothoracic areas as well as occipital headaches. Paraesthesia and numbness may be present in the entire hand region or parts of it. Often, using the arms in an elevated position exacerbates the symptoms, and reports are of a heavy, tired, aching sensation along with numbness or paraesthesia. Common clinical presentation of TOS includes (1) numbness/tingling in ring and small finger but can encompass entire hand; (2) paraesthesias at night and/or during daily activities; (3) vague pain in the uninvolved extremity can occur in the hand, elbow, shoulder, and/or cervical spine; (4) subjective reports of hand/arm weakness, especially with arms raised overhead; and, (5) subjective reports of swelling in the absence of true swelling.

Electrodiagnostic tests have been disappointingly unreliable for diagnosing TOS, except in more severe cases.²⁷ On the other hand, electrodiagnostic test results should be negative in the case of myofascial involvement. Needle electromyography (EMG) was the most sensitive to a neuropathy caused by TOS, but was positive only in more chronic and severe cases.²⁸

Diagnosis is based on a total clinical picture, comprised of a careful meticulous history, review of medical records, and clinical examination. Clinical examination also includes tenderness over the scalene muscles, anterior chest wall, a positive Tinel sign over the brachial plexus in the cervical spine, reduced sensation to light touch in the fingers, and a positive response to several provocative maneuvers that put stress on the brachial plexus to elicit symptoms. The most common provocative maneuvers used include Adson test, costoclavicular maneuver, Wright test (hyperabduction test), and Roos test.²⁹ Roos³⁰ reported that the only maneuver, which he found helpful, was a test that required the patient to hold the hands up with both arms abducted to 90° and the elbows bent at 90° as if told to “stick ‘em up.” A study of 200 healthy volunteers observed that vascular responses were too common to be a reliable indicator of TOS. The Adson maneuver produced 13.5% positive responses, the costoclavicular maneuver produced positive responses in 47%, and the hyperabduction maneuver in 57% of normal extremities.³¹ On the other hand, evaluation of neurologic responses produced positive results to the Adson maneuver in only 2% of normal extremities, to the costoclavicular maneuver in 10%, and to the

hyperabduction maneuver in 16.5% of normal extremities. Nevertheless, identification of the structure suffering compression does not by itself identify the cause of compression.

2.3. Trigger Points and Thoracic Outlet Syndrome

Abnormal tension of the scalene muscles is frequently identified as being responsible for the symptoms of TOS, but why the scalene muscles become abnormally tense remains enigmatic in most of the literature. Trigger points are not considered as a potential source of this syndrome. In addition, the scalene muscles cannot exhibit high tension but only TrPs. In fact, the referred pain elicited by the scalene muscles themselves can mimic TOS pain symptoms. In addition to the scalene muscles, other muscles can have TrPs that refer pain in locations mimicking TOS symptoms. The four primary muscles that can mimic TOS symptoms and that are particularly confusing if several of them develop TrPs at the same time are the pectoralis major, latissimus dorsi, teres major, and the subscapularis muscles.³² Because all of these muscles commonly develop TrPs and are infrequently, if ever, examined by surgeons as a likely source of TOS symptoms, it is not surprising that some patients who undergo surgery for TOS, in whom no anatomic abnormality is clearly found, experience limited clinical benefit from surgery. Also, overlooking active TrPs in conservative treatment helps account for many of those patients who do not respond to conservative treatment. In addition, because pectoralis minor TrPs are likely to be associated with scalene TrPs, the arterial flow may suffer a double entrapment where the subclavian artery emerges from the thorax wedged between the first rib and the tendon of the anterior scalene muscle and where the axillary artery hooks behind the pectoralis minor muscle. Nevertheless, entrapment of the axillary artery is more often due to TrP activity and taut bands of the pectoralis minor muscle than to TrP activity of the scalene muscles.

The presence of TrPs does not exclude a real TOS. For instance, the increased angulation of the neurovascular bundle over a cervical rib instead of the first rib increases its vulnerability to entrapment. An increased tension caused by TrPs will likely cause more severe symptoms when a cervical rib is present. Release of the TrPs may also relieve the symptoms they precipitated, if the TrPs have not been allowed to persist for too long a time and if the tension has not produced permanent nerve damage.

Conservative treatment for TOS almost always includes a treatment procedure that would be likely to release scalene muscle tightness, usually a stretching exercise or a myofascial release procedure. Both can be effective ways of inactivating TrPs if applied in a suitable manner to release TrPs in the involved muscles. Effective management may also need to include correction of ineffective posture (particularly rounded shoulder posture), elimination of unnecessary stress on the muscles during daily activities, counsel on proper care of the muscles, mobilization of articular dysfunctions, and attention to life stresses and coping strategies. A few patients with symptoms of TOS will have anatomic abnormalities that require surgical correction for complete relief. Tardif³³ noted that scalene TrPs commonly mimicked the symptoms of a C6 radiculopathy component of TOS and that pectoralis minor TrPs can create symptoms of medial cord compression. Walsh³⁴ identified

TrPs in the scalene, supraspinatus, infraspinatus, and pectoral muscles as the most common muscles that mimic TOS. Unfortunately, no studies have critically tested a TrP-based approach as a nonoperative intervention for TOS.

3. SUBACROMIAL PAIN SYNDROME

3.1. Overview

Shoulder pain is a significant health problem with a prevalence of 25% in the general population.³⁵ Neither rotator cuff disease nor impingement syndrome, as each term is commonly used, is a specific or satisfactory diagnosis. Tekavec et al³⁶ found that the most prevalent diagnosis in individuals with shoulder pain is subacromial pain syndrome. The societal burden of shoulder pain is substantial. The annual cost of a patient with shoulder pain is €4 139 in primary health care in Sweden,³⁷ and the direct costs for the treatment of shoulder disorders in the United States are \$7 billion.³⁸ Reports of shoulder pain are also a common reason for patients to seek therapy. In a survey of US outpatient physical therapy services, 11% of 1 258 patients indicated the shoulder as their chief area of pain.³⁹ Below is a review and analysis of problems of the rotator cuff in relation to muscle imbalance, particularly applicable to the supraspinatus, infraspinatus, teres minor, and subscapularis muscles as it relates to shoulder impingement.

Rotator Cuff Syndrome and Shoulder Impingement

The rotator cuff consists of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles and it is considered the main stabilizing complex of the glenohumeral joint. Traditionally, the rotator cuff muscles were thought of as humeral head depressors maintaining a physiologic subacromial space against mainly the deltoid muscle imparting superior translation. However, the rotator cuff muscles are poorly positioned to produce effective depression of the humeral head.⁴⁰ More likely, the main role consists of producing proper compressive forces required for concavity compression of the humeral head into the concave glenoid fossa. This is clinically important for avoiding superior translation of the humeral head induced by the deltoid muscle that may easily cause narrowing of the subacromial space and subsequent impingement.⁴¹

Shoulder impingement as a clinical entity is currently under debate because no clear evidence of real impingement has been found. The coracoacromial arch defines the subacromial space consisting of the acromion and coracoid processes with the coracoacromial ligament spanned between them. The subacromial bursa, the rotator cuff tendons, and the tendon of the long head of the biceps brachii muscle are located between the head of the humerus and the coracoacromial arch, in a space measuring 1 to 1.5 cm on radiographs taken in the anatomic position.⁴¹ Variations in the shape of the acromion have been suggested as playing a role in shoulder impingement, although classification of acromion morphology has been questioned.⁴² A study conducted on 216 patients found

that the presence of an acromial spur was associated with the presence of a full-thickness rotator cuff tear in both symptomatic and asymptomatic patients.⁴²

In primary impingement, the combination of repetitive overhead activity and external narrowing of the subacromial space is thought to be responsible for tendon injury. Mechanical compression occurs between the rotator cuff tendons and the coracoacromial arch. Secondary impingement is mostly associated with glenohumeral instability. Congenital laxity, labral and rotator cuff tears, and posterior glenohumeral capsular tightness have all been implicated in secondary impingement.⁴³ The most common type of shoulder impingement is the posterosuperior internal impingement, whereby the articular side of the supraspinatus tendon is impinged between the posterosuperior labrum, the glenoid and the greater tuberosity.⁴⁴ With coracoid impingement, the tendon of the subscapularis muscle and, occasionally, the long head of the biceps brachii tendon are impinged between the lesser tuberosity and the coracoid process. This impingement occurs during flexion, internal rotation, and cross-body adduction of the shoulder.⁴⁵

Another diagnosis that is commonly seen is bursitis, sometimes identified specifically as subdeltoid or subacromial bursitis. The subdeltoid bursa is large and lies beneath the deltoid muscle against the joint capsule. The subacromial bursa is more superficial and lies between the deep surface of the acromion and the tendon of the supraspinatus muscle overlying the capsule.²¹ Bursitis is diagnosed by palpation of tenderness directly under the acromial process with the arm in the neutral resting position at the patient's side and duplicating the patient's pain at the point of pressure. However, by palpation, bursitis alone is indistinguishable from supraspinatus enthesopathy. In fact, the tendinous attachment region of the supraspinatus muscle is in contact with the bursa. Enthesopathy (nociceptive sensitization) of that muscle attachment may become inflammatory enthesitis that, by its direct contact, causes inflammatory changes in the subacromial bursa.

Finally, some patients with subacromial pain syndrome develop calcific tendinopathy. In the shoulder, the supraspinatus tendon is most commonly affected with deposits located around 1 to 1.5 cm proximal to its humeral insertion. Symptoms are due to exudation of cells, rupture of the calcific deposit into the bursa, and vascular proliferation. An acute episode can last up to 2 weeks, but the subsequent subacute episode with pain and restricted movement lasts 3 to 8 weeks.⁴⁶

3.2. Initial Evaluation of a Patient with Subacromial Pain Syndrome

Subacromial pain syndrome often presents with a poorly localized pain in the anterior to lateral part of the shoulder. In some patients, particularly those developing sensitization mechanisms, symptoms can spread toward the upper extremity, particularly during overhead movements.⁴⁷ The pain may be present spontaneously at rest or at night when the patient sleeps on the affected shoulder, but it is usually most pronounced with motion, especially overhead. Generally, the intensity of the pain is moderate, but in some patients, severe pain may indicate pathology requiring referral for further medical screening.

Clinical diagnosis of subacromial pain syndrome has mostly focused on rotator cuff or

shoulder impingement symptoms. In fact, there is consensus that a cluster of tests should be used for diagnosis of this syndrome. The painful arc sign is the test most commonly used in clinical practice for diagnosis of subacromial pain syndrome. A painful arc sign is defined as pain on active frontal or scapular plane elevation that is most pronounced during midrange (60°-120°). Sensitivity and specificity of the painful arc sign was 0.45 to 0.98 and 0.10 to 0.79, respectively, for rotator cuff tear diagnosis and 0.33 to 0.71 and 0.47 to 0.81 for shoulder impingement.⁴⁸ A recent meta-analysis found that a positive painful arc test during abduction had a +LR of 3.7 (95% CI 1.9-7.0).⁴⁹ In another review, Alqunae et al⁵⁰ reported the psychometric data for the following clinical tests: Hawkins–Kennedy test (+LR 1.70, 1.29-2.26), Neer’s sign (+LR 1.86, 1.49-2.31), empty can test (pooled specificity 0.62), drop arm test (pooled specificity 0.92), and lift-off test (pooled specificity 0.97).

In individuals with suspicion of rotator cuff tear, the Dutch Orthopedic Association Clinical Practice Guideline for subacromial pain syndrome recommends the use of ultrasound for the diagnosis.⁵¹ A literature review by Dinnes et al⁵² found that for full-thickness tears, sensitivity and specificity ranges from 0.58 to 1.00 and from 0.78 to 1.00 respectively, suggesting that ultrasound can be used as a confirmatory diagnostic test for subacromial pain syndrome. Magnetic resonance imaging can be also used for proper diagnosis of rotator cuff tear, but it is more expensive than ultrasound and can produce false-positives.

After proper diagnosis of the condition, the clinician should examine the glenohumeral joint, shoulder girdle and scapula, cervical spine, thoracic spine, and the ribs for the presence of joint hypomobility and scapular dyskinesia. In addition, TrPs should be considered to be among the most common causes of shoulder pain. In fact, the Dutch Orthopedic Association Clinical Practice Guideline for subacromial pain syndrome specifically recommends examination and management of TrPs.⁵¹ It is important to determine whether a diagnosis has been properly conducted, or the symptoms experienced by the patient can be exclusively related to TrPs. For instance, TrPs in the biceps brachii muscle refer pain to the long bicipital tendon area. Therefore, tenderness to palpation of the bicipital tendon in the referred pain area from TrPs in the biceps brachii muscle may be mistaken for bicipital tendinitis or subdeltoid bursitis. Although a positive Yergason’s sign (pain in the proximal aspect of the bicipital groove when the patient supinates the forearm against resistance) is usually interpreted as a sign of bicipital tendinitis, it can be also referred pain elicited by biceps brachii TrPs. Similarly, tenderness elicited by deep palpation over the deltoid muscle, but referred from biceps brachii muscle TrPs, may be misidentified as subdeltoid bursitis.

3.3. Trigger Points and Subacromial Pain Syndrome

It seems clear that the presence of TrPs in the shoulder musculature can play a relevant role in the sensory and motor symptoms in individuals with subacromial pain syndrome.⁵³ For instance, active TrPs in the infraspinatus, supraspinatus, teres minor, or subscapularis muscles may cause referred pain, which can be felt deep in the shoulder and can mimic

symptoms like subacromial bursitis or rotator cuff tendinopathy.⁵⁴ Development of TrPs in the shoulder muscles may be caused by different circumstances, for example, sudden contractions,⁵⁴ overload during sports,⁵⁵ shoulder surgery,⁵⁶ or even thorax surgery.⁵⁷

In a reliability study on palpation of the shoulder muscles, Bron et al⁵⁸ reported that the most reliable features of TrPs were the referred pain sensation and jump sign with a percentage of pair-wise agreement of 70% (range 63-93%) and 70% (range 67-77%), respectively. This data suggests that identification of TrPs in the shoulder girdle muscles is reliable. Trigger point prevalence in the shoulder muscles has been explored in different studies. Bron et al⁵⁹ included individuals with nontraumatic unilateral shoulder pain, without specifying particular diagnosis, and found that all patients exhibited a median number of six active TrPs. Trigger points were found to be present in the infraspinatus, upper trapezius, deltoid, teres minor, and middle trapezius muscles. In this study, the number of active TrPs was associated with pain-related disability, pain intensity, and the duration of the shoulder pain supporting a potential role of active TrPs in this condition. In another study, the same authors observed that manual therapy targeting active TrPs in the shoulder musculature was more effective than a wait-and-see strategy for improving pain and function in individuals with nonspecific shoulder pain in the short term.⁶⁰ Other studies have also demonstrated that proper management of TrPs in the shoulder muscles is effective for shoulder pain and disability.^{61, 62} Another study observed the presence of bilateral TrPs in the infraspinatus muscles in people with chronic unilateral myofascial shoulder pain supporting the role of sensitization mechanisms in TrP pain.⁶³ Active TrPs were only found in the symptomatic side, but the most interesting finding was the presence of latent TrPs in the non-symptomatic side. Another important finding from this study was the presence of multiple, rather than single, active TrPs in the infraspinatus muscle, underscoring the importance of searching for multiple active TrPs within one muscle in patients with myofascial pain.⁶³

Other studies including people with specific diagnosis of shoulder impingement have observed similar data. Hidalgo Lozano et al⁶⁴ found that patients with shoulder impingement had a larger number of both active and latent TrPs than did healthy subjects and that the presence of active TrPs was associated with greater shoulder pain intensity. Active TrPs within the supraspinatus, infraspinatus, and subscapularis muscles were the most prevalent. A relevant finding for clinical practice was that the presence of active TrPs in some muscles was related to pain during specific movements of the shoulder. For instance, the presence of active TrPs in the infraspinatus muscle was related to more pain at rest, whereas the presence of active TrPs in the biceps brachii muscle was related to more pain during arm elevation.⁶⁴ Another study found that people with unilateral shoulder impingement exhibited latent TrPs in the unaffected shoulder.⁶⁵ Patients with shoulder impingement showed at least four active TrPs in the shoulder musculature, and the number of TrPs was related to shoulder pain. In this study, the supraspinatus, infraspinatus, subscapularis, and deltoid muscles were the most affected by active TrPs. Table 33-1 summarizes which muscles exhibit active TrPs in patients with subacromial pain syndrome.

Table 33-1 Active Myofascial Trigger Points Found in Subacromial Pain Syndrome.

Nonspecific Shoulder Pain
Infraspinatus 77% active TrPs Upper trapezius 58% active TrPs Deltoid 40% active TrPs Teres minor 35% active TrPs Middle trapezius 30% active TrPs
Shoulder Impingement
Supraspinatus 67% active TrPs Infraspinatus 42-48% active TrPs Upper trapezius 44% active TrPs Subscapularis 40-42% active TrPs Scalene 40% active TrPs

The table summarizes the percentage of active TrPs found in patients with nonspecific shoulder pain⁵⁹ and those with medical diagnosis of shoulder impingement.^{64, 65}

There is clear evidence supporting a potential role of active TrPs in shoulder pain. In addition, the fact that exercise and manual therapies are the most common therapeutic strategies used for the management of this condition⁶⁶ supports this assumption. Exercise programs are supported in systematic reviews for producing improvements in both pain and function in individuals with shoulder pain.⁶⁷

4. SCAPULAR DYSKINESIA

4.1. Overview

Scapular dyskinesia can be defined as a motor alteration of the normal recruitment pattern of muscle contraction of the shoulder girdle musculature. It seems that a consistent recruitment pattern of the shoulder muscles during abduction in the scapular plane is found in asymptomatic shoulders.^{68, 69} The upper trapezius muscle is activated first, followed by serratus anterior, middle trapezius, and finally, the lower trapezius muscles. The temporal characteristics are delayed but not changed by fatigue in asymptomatic subjects.⁶⁸

Reflecting the role of the glenohumeral joint as part of the multi-joint shoulder girdle, scapular dyskinesia has been suggested as a potential cause for shoulder pain. In fact, a reasonably consistent pattern of decreased activity has been demonstrated in both the lower trapezius and serratus anterior muscles and increased activity in upper trapezius muscles in individuals with shoulder pain.⁶⁹⁻⁷² In a more recent study, Kibler et al⁷³ observed that inhibition of lower trapezius and serratus anterior muscles was a nonspecific response to shoulder pain, irrespective of the underlying pathology. Decreased activity in the lower

trapezius and serratus anterior muscles associated with arm elevation^{70, 74} in patients with shoulder dysfunction supports the observation of delayed or reduced upward rotation in the clinical setting. Increased upper trapezius muscle activity under heavier load⁷⁰ and in the upper ranges of elevation⁷⁴ possibly reflects a compensation for decreased activity in lower trapezius and serratus anterior muscles and/or an attempt to overcome the increased tone in the antagonists.

External rotator fatigue significantly reduced scapular upward rotation, posterior tilt, and external rotation during shoulder arm elevation, thereby decreasing the amount of subacromial space.⁷⁵ Cools et al⁷¹ showed significant delays in activation of the middle and lower trapezius muscles in individuals with shoulder impingement. Further, indicating the possible role of pain-related inhibition in scapular dyskinesia, Falla et al⁷⁶ demonstrated that the injection of hypertonic saline injection in the upper trapezius muscle was sufficient to result in altered motor control of this muscle, not only locally at the site of pain but also in non-painful regions within the same muscle and on the contralateral side. A modification of motor strategy resulting in compensatory muscle activity is likely to lead to muscle overload and perpetuate pain and dyskinesia.

Nevertheless, clinicians should consider that not all responses to shoulder pain are consistent,^{71, 74} possibly reflecting the different patterns demonstrated in subgroups within sample populations with the same medical diagnosis.⁶⁹ The observation of variations in patterns of muscle activity supports the need to address each patient's impairment individually during assessment.

4.2. Initial Evaluation of a Patient with Scapular Dyskinesia

Several exploratory tests can be used for proper evaluation of scapula kinematics. The Apley's test (flexion, abduction, external rotation) may be used to grossly evaluate for TrP involvement in the shoulder girdle musculature. The test is performed by placing the forearm and hand of the affected side behind the head and reaching as far toward the opposite scapula as possible (Figure 21-3B). This test requires full active abduction and external rotation of the arm at the glenohumeral joint. It also requires normal scapular mobility. If the clinician looks closely at how the subject raises the arm, scapulohumeral rhythm can also be assessed. If no dysfunction is present, the fingertips should reach to the opposite shoulder blade.

Moving the hand to the end position or holding this position may be painful because of strong contraction of the abductors and external rotators of the shoulder that are in the shortened position. However, movement also may be limited by a tight adductors or internal rotators. Although any of these muscles might cause pain-limited restriction during this test, the muscles most likely to limit the movement in this way are the strongly contracted infraspinatus and middle deltoid muscles. In this case, the pain is most likely to be in the immediate vicinity of the TrPs. The test movement also passively stretches the subscapularis muscle and if that muscle has TrPs, it is likely to refer pain behind the shoulder and to the wrist. Trigger points of the latissimus dorsi muscle can also cause pain

at the end of its extensive range of motion only if no other muscle were restricting the movement. Clinicians are encouraged to consider the presence of TrPs in all clinical tests used for assessing motor impairments in scapular kinematics.

4.3. Trigger Points and Scapular Dyskinesia

Examination of all components of the neuromuscular system including dysfunction of synergistic control, timing of muscle activation, patterns of co-contraction, and proprioceptive control in a patient with shoulder pain is clinically recommended, especially pain of long duration and/or high intensity. Although there is no study investigating the presence of TrPs in patients with scapular dyskinesia, there is clear evidence showing that TrPs can cause altered motor control patterns, accelerated muscle fatigability, and increased motor activation in the affected and related musculature.⁷⁷ This relationship is particularly and clinically important in the case of latent TrPs, because latent TrPs do not produce sensory pain symptoms but they clearly induce motor disorders. For instance, Ibarra et al⁷⁸ observed that intramuscular, but not superficial, EMG activity of antagonist muscles (ie, posterior portion of the deltoid muscle) was significantly higher at rest and during agonist contraction (ie, anterior portion of the deltoid muscle) with the presence of latent TrPs in the related muscle, signifying reduced antagonist reciprocal inhibition. Ge et al⁷⁹ found that latent TrPs were associated with an accelerated development of muscle fatigue, as depicted by early decrease in intramuscular EMG mean power frequency, and also by simultaneously overloading active motor units close to the TrP expressed as early and significant increase in surface EMG root mean square amplitude. In another study, the same authors observed that latent TrPs were also associated with an increased intramuscular, but not surface muscle, activity during synergistic muscle contraction.⁸⁰ This study explains that active motor units from latent TrPs have to work more than the active motor units from non-TrP fibers to maintain the similar level of force output, leading to an incoherent muscle activation pattern of synergist muscle fibers. Therefore, a chaotic muscle recruitment pattern may lead to muscle overuse and premature fatigue of musculature harboring TrPs. In such a scenario, TrPs provide a potent source for disturbance of muscular imbalances observed in people with scapular dyskinesia. This is also related to the fact that TrPs in some muscles, for example, the lower portion of the trapezius muscle, induce muscle inhibition.

Different studies have demonstrated that the presence of latent TrPs in the neck/shoulder muscles induces change in motor recruitment patterns and decreases efficiency of movement during scapular plane elevation of the shoulder girdle musculature during unloaded and low-load tasks.^{77, 81, 82} These studies found that people with latent TrPs exhibited different temporal sequences of activation in the scapular and rotator cuff muscles during upper extremity low-load tasks. However, there were inconsistencies in the order of muscle activation. The only common feature observed was early activation of the infraspinatus muscle.^{77, 81, 82} Current findings suggest that in individuals with latent TrPs, the timing of muscle activation is altered and more variable not only in the muscles

containing the TrPs (upward scapular rotators) but also in functionally related muscles (infraspinatus muscle as a glenohumeral stabilizer and middle deltoid muscle as abductor of upper extremity) during scapular plane elevation. A recent study confirmed that the presence of latent TrPs in the upper trapezius muscle produces a delayed timing activation of the upper trapezius and serratus anterior muscles during rapid arm elevation in all planes of movement.⁸³

These changes in timing recruitment may predispose individuals to increased risk of subacromial impingement. It would be reasonable to expect that treatment of TrPs may lead to normalization of motor activation patterns and facilitate spontaneous recovery of shoulder pain, either without exercising or by making therapeutic exercise more effective. This thinking was partially confirmed in a follow-up experiment when half of the subjects presenting with latent TrPs were treated, deactivating their TrPs using dry needling and passive muscle stretching.⁸¹ The individuals in whom latent TrPs were treated demonstrated a normalized motor recruitment pattern, resulting in no significant differences in the timing of muscle activation compared with the control group.

5. FROZEN SHOULDER

5.1. Overview

The descriptive terms “frozen shoulder” and “adhesive capsulitis” are not specific diagnoses and frequently are based only on the presence of a painful shoulder that exhibits severely restricted range of motion in all directions. The label “frozen shoulder,” when presented as the diagnosis that accounts for the patient’s symptoms, serves as a warning that the patient is in need of a more specific diagnosis. The etiology of this condition is unknown, and it is commonly differentiated between primary and secondary frozen shoulder. Primary frozen shoulder is idiopathic and not related to other diseases; whereas secondary frozen shoulder is related to known systemic pathology, such as diabetes mellitus, thyroid disease, Parkinson’s disease, post-surgery, post-trauma, or after long periods of immobilization. It can be difficult to differentiate, but post-surgical shoulder stiffness is not the same as secondary post-surgical frozen shoulder.

Although the pathologic process in primary frozen shoulder is unclear, it is generally accepted as the presence of an underlying inflammatory process of the synovial membrane followed by a fibrotic reaction of the fibrous layer of the glenohumeral capsule. Especially in the area of the coracohumeral ligament and the rotator cuff interval, scar and contracture formation is initiated by the expression of vimentin (a cytocontractile protein, usually seen in fibrocytes), whereas in the entire joint capsule there is fibroplasia (thickening of the joint capsule) without contraction.^{84, 85} Nevertheless, despite all the scientific research done on primary frozen shoulder, the trigger for the cascade of inflammatory and fibrogenetic processes is still unclear.

5.2. Initial Evaluation of a Patient with Frozen Shoulder

Primary frozen shoulder is mainly characterized by restriction of shoulder motion without major shoulder injury; global stiffness of the shoulder joint in all directions without the loss of strength, joint stability, or joint surface integrity; and plain shoulder radiographs showing a normal glenohumeral joint space and no peri-articular abnormalities. The pain is usually experienced in the shoulder region, the deltoid muscle insertion, and upper arm, but it often refers to the neck and more distal regions of the upper extremity. In the freezing phase, the pain is felt during rest and intensified during movement and during sleep. The amount of pain depends on the clinical phase of the disease. In fact, clinical diagnosis of a primary frozen shoulder includes proper recognition of each phase of the condition (freezing, frozen, and thawing) and the practitioner's clinical challenge is formed by the discrimination of the exact phase and appropriate duration of symptoms or signs. Frozen shoulder is generally considered a self-limiting disease with a mean average duration of 1 to 3 years, but a part of the population presents with substantial limitations in shoulder passive range of motion for up to 10 years after the onset of the condition.⁸⁶

Physical examination of a patient with frozen shoulder includes palpation of the cervical spine and the shoulder girdle for tendon and ligament tenderness. The shoulder should be examined for signs of muscle atrophy, former trauma, and swelling. During assessment of shoulder mobility, attention should be paid to the contribution of the glenohumeral joint isolated to active and passive range of motion. Clinicians should consider that in the freezing phase, pain is the most limiting factor and joint restriction of glenohumeral motion may be less clear. In the frozen phase, the characteristic global limitation of passive range of motion of the glenohumeral joint is present. In the thawing phase, the global limitation fades out and usually the contracture of the rotator interval causes a marked limitation of external rotation. It is interesting to note that all these clinical signs can be also a manifestation of TrPs in the shoulder girdle musculature, particularly the subscapularis, supraspinatus, and infraspinatus muscles.

5.3. Trigger Points and Frozen Shoulder

Clinicians should consider that the primary symptoms of frozen shoulder, namely shoulder pain referred to the upper extremity and restricted range of motion, are also primary symptoms of active TrPs in the shoulder girdle musculature. For instance, the shoulder becomes more restricted in external rotation (up to 45° or more) when the subscapularis muscle exhibits active TrPs. Trigger points in the infraspinatus muscle seem to be responsible for shoulder pain during internal rotation; whereas TrPs in the teres major muscle may be responsible for a restriction in abduction. Probably, the subscapularis muscle is the most important muscle to consider in frozen shoulder. Lewit⁸⁷ voiced the observation of clinicians skilled at identifying TrPs that “painful spasm of the subscapularis, with TrPs, accompanies frozen shoulder from the onset.” Because the humeral tendinous attachment region of the subscapularis is not accessible to direct palpation, its tendency to develop enthesitis is not well recognized. The humeral attachment of the subscapularis tendon lies in close approximation to the subscapular bursa. Because adhesions in the

subscapular bursa are identified as a major component of adhesive capsulitis or frozen shoulder, it is possible that a chronic enthesitis of the subscapularis muscle adjacent to its bursa could induce an inflammatory reaction that could lead to fibrosis of the bursa, which requires either forceful manipulation, inflation of the bursa, or arthroscopic surgery to release it. In this case, the stage of fibrosis could be prevented by prompt recognition and treatment of the subscapularis TrPs.

In addition, one potential reason for the shoulder becoming so painful and motion so limited when a patient develops subscapularis TrPs is that other shoulder girdle muscles, for example, supraspinatus, infraspinatus, or deltoid muscles, can be also involved, adding their pain patterns and movement restrictions. For instance, the supraspinatus muscle is prone to develop enthesopathy or enthesitis. Similar considerations apply to supraspinatus TrPs and enthesitis of the supraspinatus tendon in the region where it blends with the joint capsule. Both the subacromial bursa and the coracohumeral ligament lie in close approximation to this region of supraspinatus attachment. Therefore, proper treatment of TrPs could potentially prevent subsequent pain, disability, and expense in individuals with frozen shoulder.

The frozen shoulder literature often refers to the importance of trying conservative interventions first and frequently identifies physical therapy as an essential part of a conservative care plan. When a patient presents with a diagnosis of adhesive capsulitis or frozen shoulder, clinicians need to consider TrP as a potential source of symptoms. Nevertheless, specific identification of subscapularis TrPs as a focus of therapeutic attention in frozen shoulder has been rarely mentioned in the literature, and no controlled trials that specifically addressed the TrP component of frozen shoulder have been found. There is only one case report describing the clinical reasoning behind the use of TrP dry needling in the treatment of an individual with adhesive capsulitis.⁸⁸ This case report observed a rapid improvement in pain and range of motion following the initiation of dry needling applied to upper trapezius, levator scapula, deltoid, and infraspinatus muscles. Surprisingly, there is no mention of the subscapularis muscle TrPs in this case report.

6. NECK PAIN (STIFF NECK)

Clinically, patients can present with cervical spine dysfunction with a predominant symptom of stiffness in the neck (see Chapter 18). Patients with a “stiff neck” syndrome exhibit extremely reduced cervical range of motion (some patients cannot move their neck) and they perceive their neck as feeling “like a stick.” One cause of this syndrome may be increased tone in the cervical muscles that cross the craniocervical and cervicothoracic junctions vertically. The levator scapulae muscle is the main example. Active trigger points (TrPs) in both levator scapulae muscles combined with an increased muscle tone by their respective taut bands can precipitate a “stiff neck” syndrome. In addition, the splenius cervicis, scalenus medius, and iliocostalis cervicis muscles can also be involved. Contrary to what might be expected, rhomboid TrP activity is rarely associated with levator scapulae muscle involvement. If the patient’s head is strongly tilted to one side (wry neck), TrPs in

the sternocleidomastoid muscle are more likely to be responsible than are levator scapulae TrPs.

The common physical finding of crepitation and the relatively frequent presence of bursae near the upper (superior) angle of the scapula indicate that the tenderness and referred pain elicited may be caused by a bursitis instead of, or in addition to, enthesopathy caused by unrelieved tension of taut bands associated with TrPs in the levator scapulae muscle. Nevertheless, tightness of the levator scapulae muscle or taut bands associated with TrPs can be also responsible for crepitation in the superior angle of the scapula. In such cases, release of TrPs in the muscle belly of the levator scapula muscle is critical for relief of these reported or observed symptoms.

It is known that referred pain from zygapophysial joints can appear confusingly similar to that of TrPs in muscles at approximately the same segment.⁸⁹ The referred pain of levator scapulae TrPs overlaps the lower two-thirds of referred pain from the C4-C5 zygapophysial joints but also extends more inferiorly.⁹⁰ In fact, articular dysfunctions commonly associated with levator scapulae TrPs can be at C3, C4, C5, or C6 levels. However, there are important differences. Even though joints and muscles are innervated by the same or overlapping neural segments, myofascial pain referral patterns can be distinctively different for different muscles innervated by the same neural segments. The patterns are not always limited to the sclerotomes or myotomes of the segments that innervate the muscle. Trigger points are confirmed by physical examination of the muscle, whereas zygapophysial joint dysfunction is assessed by passive manual tests including evaluation of end-feel, tissue resistance, and reproduction of the patient's symptoms.

The etiology of scapulocostal syndrome has been considered enigmatic by many authors in the past, but a number of authors have empirically attributed the symptoms to TrPs.^{91,92} Ormandy⁹³ presented a review of this diagnosis including anatomic outlines of the muscles this author considered responsible: the levator scapulae, rhomboid minor, subscapularis, and trapezius muscles. It seems that the levator scapulae muscle is the major, if not the primary, cause of this condition.

Section 4

Forearm, Wrist, and Hand Pain

Wrist Extensor and Brachioradialis Muscles

“Pseudo Tennis Elbow”

Orlando Orlando Mayoral del Moral and Enrique Lluch Girbés

1. INTRODUCTION

The wrist extensor muscles are anatomically located in the dorsal forearm and include the extensor carpi radialis longus (ECRL), extensor carpi radialis brevis (ECRB), and the extensor carpi ulnaris (ECU) muscles. The main function of these muscles is wrist extension with a component of either radial or ulnar deviation. Despite also being located in the dorsal forearm, the brachioradialis muscle does not exert its main function at the wrist; its primary role is to flex the elbow, regardless of forearm position. The referred pain elicited by trigger points (TrPs) from the wrist extensor and brachioradialis muscles spreads upward to the lateral epicondyle and downward toward the dorsum of the forearm, wrist, and base of the thumb, in the space between the thumb and the index finger. Symptoms may be exacerbated by repetitive lifting and grasping activities, as well as sleeping postures that promote elbow and wrist flexion. Activation and perpetuation of TrPs in the wrist extensor and brachioradialis muscles are caused by repetitive forceful grasping and sporting activities. The larger the object being grasped, and the greater the amount of ulnar deviation required of the hand, the more likely the muscles are to develop TrPs. Compelling evidence supports a role of myofascial pain derived from the wrist extensor and brachioradialis muscles as part of the etiology of lateral elbow pain or lateral epicondylalgia. Differential diagnosis includes true tennis elbow, ECRB tendinopathy, local arthritis, radiocapitellar pathology, radial tunnel syndrome, posterior interosseous nerve syndrome, cervical radicular pain or radiculopathy (C7), and de Quervain syndrome. Corrective actions include eliminating strain of the involved muscles, correcting grasp, establishing a home program of TrP self-pressure release and self-stretch exercises, and the gradual resumption of normal activities after inactivating the TrPs.

2. ANATOMIC CONSIDERATIONS

The muscles of the forearm can be divided into two major compartments: the flexors and extensors. The extensor muscles can be further divided into five dorsal compartments: (1) a radial compartment enclosing the brachioradialis muscle; (2) a radial compartment enclosing the ECRB and ECRL muscles; (3) an abductor compartment with the abductor pollicis longus and extensor pollicis brevis muscles; (4) a central compartment with the extensor digitorum, extensor digiti minimi, extensor pollicis longus, and extensor indicis muscles; and (5) an ulnar compartment housing the ECU muscle.¹

The wrist extensor musculature is located over the radial and ulnar aspects of the forearm. The ECRL and ECRB muscles are located radially and the ECU muscle is located ulnarly. Together with the brachioradialis, supinator, extensor digitorum, and extensor digiti minimi muscles, they constitute the extensor-supinator muscle group.² Each muscle belonging to this group originates near or directly onto the lateral epicondyle of the humerus. Anatomic variations of radial wrist extensor muscles are common, and several varieties from the norm are documented in the literature.³⁻⁷ The tendons of the ECRB, ECRL, and brachioradialis muscles are quite useful in tendon transfer operations, such as in correction of finger clawing and restoration of thumb opposition.⁷⁻⁹ The extensor retinaculum prevents the extensor tendons from “bowstringing” away from the radiocarpal joint during functional activities. Under the extensor retinaculum are six fibro-osseous tunnels that contain the extensor tendons and their synovial sheaths. The tendons of the ECRL and ECRB muscles are within the same tunnel but have independent synovial sheaths.¹⁰

Extensor Carpi Radialis Longus

The ECRL muscle originates from the distal third of the lateral supracondylar ridge of the humerus, between the lateral epicondyle and the attachment of the brachioradialis muscle (Figure 34-1A).^{2,9,11,12} Distally, the ECRL muscle inserts onto the base of the 2nd metacarpal bone on its dorsoradial aspect and may also send slips to the 1st and 3rd metacarpal bones. The muscle fibers extend one-third of the length of the forearm, and its tendon extends the remaining two-thirds.¹³

Figure 34-1. The relations of the hand extensor muscles and part of the radial nerve in the right forearm. A, Dorsal view showing the attachments of the extensor carpi radialis longus and brevis, and extensor carpi ulnaris muscles. B, Lateral view showing the deep branch of the radial nerve before it passes beneath the fibrous arch formed by the proximal attachments of the extensor carpi radialis brevis (light red), and showing the normal course of the superficial (sensory) branch. C, Variant course of the superficial branch of the radial nerve *through* the (reflected) extensor carpi radialis brevis muscle. Adapted from Kopell HP, Thompson WA. *Peripheral Entrapment Neuropathies*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1963.

Extensor Carpi Radialis Brevis

The ECRB muscle arises mainly from the lateral epicondyle of the humerus, radial

collateral ligament, intermuscular septa and is covered by a strong aponeurosis.¹³ The ECRB muscle lies deep to the belly of the ECRL muscle.^{2,11} The belly of the ECRB muscle expands to full thickness near the junction of the upper and middle thirds of the forearm where the more lateral ECRL muscle belly fades to a tendon.¹⁴ The ECRB muscle passes behind and deep to the ECRL muscle, and under the extensor retinaculum distally, inserting onto the base of the 3rd metacarpal bone and sometimes with a slip to the 2nd metacarpal on its dorsoradial aspect (Figure 34-3A).^{2,13}

The ECRB muscle origin comprises a superficial, narrow tendinous attachment to the lateral epicondyle and a broad attachment to an intermuscular septum.^{15,16} The deeper aspect of the ECRB origin merges directly with the lateral collateral ligament that in turn also fuses with the annular ligament of the proximal radioulnar joint.¹⁶ This relationship may explain the progressive involvement of the lateral collateral ligament in some clinical presentations of lateral epicondylalgia.¹⁷ In addition, the interdigitation between the origins of the ECRB muscle and the portion of extensor digitorum muscle that extends to the 3rd digit explains Maudsley's test, that is, pain with resisted extension of the 3rd finger.¹⁸

The ECRB muscle is the only wrist extensor that has a proximal attachment with a long tendinous portion without any muscle fascicles, whereas the other wrist extensors originate as a mixture of tendon and muscle.¹² The tendinous portion of the ECRB muscle is most substantial at its origin and gradually transitions into muscle as it descends in the forearm.¹² The tendinous origin of the ECRB muscle has less vascularity in comparison with the other extensor origins, which have muscular portions, explaining why an injury to the origin of the ECRB muscle may take longer or be less likely to heal.¹² In addition, the attachment of the articular capsule to the anterior part of the ECRB muscle origin has been hypothesized to be a causative factor of lateral epicondylalgia.¹²

Proximally, the strong aponeurosis of the ECRB muscle forms a bridge of fascia, which stretches between the lateral epicondyle of the humerus and the deep fascia of the dorsal forearm. It may become thickened^{19,20} where the deep (motor) branch of the radial nerve passes beneath it to enter the supinator muscle (Figure 34-1C). Usually, the superficial radial nerve has branched off before the deep radial nerve dips beneath the ECRB muscle (Figure 34-1B). In some cases, however, the nerve divides more distally (Figure 34-1C), so that the superficial branch must penetrate the belly of the ECRB muscle to return to its own course beneath the brachioradialis muscle.¹⁹ Therefore, the radial nerve may get entrapped in the superolateral part of the ECRB muscle.²¹

Extensor Carpi Ulnaris

The ECU muscle originates proximally from the lateral epicondyle (where it forms the most medial part of the common extensor origin), the upper two-thirds of the posterior border of the ulna (by an aponeurosis shared with the flexor carpi ulnaris and flexor digitorum profundus muscles), and the overlying fascia.¹³ Distally, it attaches to a tubercle on the ulnar side of the base of the 5th metacarpal bone (Figure 34-1A).^{2,-11,13} The ECU

muscle is composed of a muscular portion and a thin membranous tendon.¹²

Brachioradialis

The brachioradialis muscle originates from the proximal two-thirds of the lateral supracondylar ridge of the humerus and along the anterior surface of the lateral intermuscular septum,¹³ distal to the spiral groove, where the radial nerve penetrates the septum at mid-arm level (Figure 34-2).^{2,18} It forms the lateral border of the cubital fossa.¹³ The muscle fibers end above mid-forearm level and transition to a flat tendon that runs distally over the anterolateral aspect of the radioulnar joint and inserts onto the lateral side of the distal end of the radius, just proximal to the styloid process.^{2,-13,18} It is composed of a muscular portion and only a thin, short tendon.¹² The brachioradialis muscle has a series-fibered architecture that consists of multiple, overlapping bands of muscle fibers in most individuals.²² In some individuals, however, a simple parallel-fibered architecture is observed.²²

Anatomic Variations

Several anatomic variations have been reported for the wrist extensor and brachioradialis muscles.³⁻⁷ In particular, different varieties of additional radial wrist extensor muscle bellies with independent tendons have been reported by Nayak et al.⁷ These additional muscles originated either from the ECRL or the ECRB muscles and were inserted at the base of the 2nd or 3rd metacarpal bones. The two classic variants described for the radial wrist extensors are named the extensor carpi radialis intermedius and extensor carpi radialis accessorius muscles.^{5,7} The extensor carpi radialis intermedius muscle originates from the ECRB muscle, becomes tendinous, and travels between the two radial extensor tendons. It inserts independently into the 2nd metacarpal bone.^{5,7} The extensor carpi radialis accessorius muscle arises from below the ECRL muscle and inserts into the 1st metacarpal bone.^{5,7}

A rare extensor carpi radialis accessorius muscle was reported originating from the ECRL muscle, passing superficially over the parent tendon, and inserting into the abductor pollicis brevis muscle.⁵ Another additional extensor carpi radialis muscle originating from the common extensor origin, between the ECRL and extensor digitorum muscles, has been noted and dubbed the extensor carpi radialis tertius muscle.⁶ The tendon of this muscle divides below the abductor pollicis longus muscle and attaches to the base of the 2nd and 3rd metacarpal bones.⁶ Mitsuyasu et al.⁴ reported the origin of the ECRB muscle from the fascia/tendon of the extensor digitorum muscle, without any of its origin at the usual location on the lateral epicondyle.

A number of variations in the attachments of the brachioradialis muscle have been reported. The distal attachment of the brachioradialis muscle may be more proximal than usual.¹³ It may fuse proximally with the brachialis muscle, and the tendon may, occasionally, divide into two or three separately attached slips.¹³ In rare instances, it is

double or absent.¹³ A variable slip of the muscle may attach distally to several carpal bones and to the 3rd metacarpal.²³

Figure 34-2. The attachments of the right brachioradialis muscle, from the radial view.

2.1. Innervation and Vascularization

Wrist Extensors

The innervation of the ECRL, ECRB, and ECU muscles is provided by branches of the radial nerve, particularly the posterior interosseous nerve.²⁴ The ECRL muscle innervation is from C6 and C7,¹³ the ECRB muscle from C7 and C8,¹³ and the ECU muscle¹³ from the C7 and C8 nerve roots.^{13, 25}

Wide variability of the innervation of the ECRB muscle has been demonstrated, with no single consistent pattern.^{9, -26, 27} The ECRB muscle can be innervated by the radial nerve, the deep branch of the radial nerve (the posterior interosseous nerve; 45%-50%), and the superficial radial nerve (25%-35%).^{9, -26, 27}

The radial artery and its branches are the principal sources of vascularization of the ECRL and ECRB muscles.^{28, 29} The ECRL muscle receives its principal vascular supply from a single branch of the radial recurrent artery.¹³ Additional vascularization comes from branches of the radial collateral branch of the profunda brachii artery and from the radial artery in the distal part of the muscle.¹³ The ECRB muscle receives its vascularization mainly from two pedicles: a single branch from the radial recurrent artery and a branch of the radial artery that arises about one-third of the way down the forearm.¹³ Additionally, branches from the radial collateral branch of the profunda brachii artery supply the muscle proximally.¹³ The undersurface of the ECRB tendon was found to be almost avascular.²⁹

Proximally, the ECU muscle receives its vascularization from branches of the radial recurrent artery, whereas distally, it is supplied by several branches from the posterior interosseous artery.¹³

Brachioradialis

Innervation for the brachioradialis muscle comes from the posterior divisions of C5 and C6 spinal nerve roots.^{2, 13}

Latev and Dalley in 2005 investigated the innervation of the brachioradialis muscle in 43 embalmed cadaveric specimens.³⁰ A wide anatomic variation was observed in the innervation pattern. A single primary nerve branch arising from the radial nerve, 30 mm proximal to the lateral epicondyle, was found in the majority of cases (46.5%). In 16 of these cases, the primary branch split into two to four secondary branches, and in four cases, there was only one branch entering the muscle.³⁰

Vascularization of the brachioradialis muscle is supplied by branches of the radial recurrent artery that pierce the posteromedial surface of the muscle.¹³ It is also supplied by branches from the radial collateral branch of the profunda brachii artery and from the radial artery in the distal part of the muscle.¹³

2.2. Function

The wrist extensors ensure effective length-tension ratios of the opposite finger flexors during their contraction for grasping. The wrist extensor muscles activate strongly in this stabilizing role to prevent wrist flexion produced by contraction of the finger flexor muscles with gripping or pinching functional activities.^{31–33} Most textbooks of anatomy briefly describe that the ECRL and ECRB muscles act as extensors and radial deviators of the wrist, and the ECU muscle acts as an extensor and ulnar deviator of the wrist.^{13,34–36} However, cadaver studies and some studies that measure topographic relationships among the tendons of the wrist extensor muscles and the axes of the joint have shown that strict actions of the ECRL muscle differ from those of the ECRB muscle.^{37–39} Furthermore, actions of the extensor muscles, including direction of the motion and force of each muscle, change depending on forearm position.³⁸

Wrist Extensors

Sagae et al⁴⁰ analyzed strict actions of the human wrist extensors using electrical neuromuscular stimulation, a method that has the ability to activate each muscle individually. This method is thought to be superior to electromyography (EMG) recording of wrist extensor muscle activity during voluntary movements because EMG shows activities of two or more wrist extensor muscles during wrist-bending motion, making it difficult to determine the activation of each individual muscle.⁴⁰ The ECRL muscle was found to act as a wrist extensor rather than a radial deviator with the forearm in a pronated position and as a wrist radial deviator rather than an extensor with the forearm in neutral and in supinated positions.⁴⁰ The ECRB muscle behaved as a wrist extensor rather than a radial deviator with the pronated, neutral, and supinated forearm positions, and the ECU muscle acts as a wrist ulnar deviator rather than an extensor with the neutral and supinated forearm positions and as a wrist ulnar deviator with the pronated forearm position.⁴⁰ Therefore, the ECRL muscle is a wrist radial deviator and extensor, and the ECRB muscle is a wrist extensor rather than a radial deviator. Supporting this argument, a previous study by Fujii et al⁴¹ found that electrical neuromuscular stimulation to the ECRL muscle induced motions of wrist extension and radial deviation regardless of the positions of the forearm.

In addition to performing extension and radial deviation of the wrist, the ECRL muscle has a good moment arm to act as an elbow flexor with the forearm pronated.⁴² The ECRL muscle may also provide some valgus force at the elbow joint.⁴² Interestingly, co-contraction of the pronator teres and ECRL muscles occurs during wrist extension movements to prevent supination of the forearm. Contraction of the ECRL muscle induced 30° to 80° supination of the forearm from the pronated position.⁴¹ Therefore, forearm supination from the pronated position should be considered one of the actions of the ECRL muscle.^{10,41}

In addition to extension and ulnar deviation of the wrist, the ECU muscle may also

provide some valgus force at the elbow joint.⁴² It is a better wrist extensor with the forearm supinated than pronated because the tendon slips anteriorly during forearm pronation.^{43, 44} It also stabilizes the wrist during thumb abduction.⁴⁵

Brachioradialis

Initially, this muscle was named the “supinator longus” on the assumption that its primary action was supination of the forearm. The brachioradialis muscle has the largest mechanical advantage of any of the elbow flexors because it inserts a long distance from the joint axis.⁴⁶ Duchenne clearly demonstrated, through stimulation studies, that it functioned chiefly as a flexor of the elbow,³⁴ which led to its current name, the brachioradialis muscle. The primary role of the brachioradialis muscle appears to be that of an elbow flexor together with the biceps brachii and brachialis muscles.¹³ Information regarding this muscle’s role as a forearm supinator or pronator remains controversial in the literature.⁴⁷ A study using fine-wire EMG electrodes in the brachioradialis muscle, along with kinematic data, showed that the greatest EMG activity recorded from the brachioradialis muscle occurs during elbow flexion, regardless of the forearm position.⁴⁷ In this same study, during tasks that required pronation and supination, the brachioradialis muscle was more active during pronation tasks compared with supination tasks, indicating a secondary function of the brachioradialis muscle as a forearm pronator.⁴⁷

Electromyographically,³⁵ brachioradialis muscle activity is usually reserved for speedy movement and lifting weight by flexing the elbow, especially if the forearm is in the neutral position. It is minimally active in slow flexion or with the forearm supinated but generates a powerful burst of activity in both flexion and extension when movement is rapid.¹³ However, none of the elbow flexors is used to counteract gravity when a weight is held in the dependent hand with the elbow straight.³⁵ The brachioradialis muscle attaches in such a manner as to prevent separation of the elbow joint with centrifugal force by contracting during rapid elbow movement. This pronounced transarticular component of its force helps stabilize the elbow joint.¹³ In contrast, the biceps brachii and brachialis muscles accelerate movement at the elbow without counteracting distraction of the elbow joint.

Historically, a specific tennis racquet grip size (following Nirschl’s recommended measurement) was linked to less risk of lateral epicondylalgia. However, Hatch et al,⁴⁸ using fine-wire EMG in different forearm musculature, including the ECRB and ECRL muscles, demonstrated that alterations in tennis racquet grip size do not have a significant effect on forearm muscle activity, and therefore racquet grip does not represent a significant risk factor for lateral epicondylalgia. Another accessory, string dampers, is often used by tennis players to supposedly reduce the amount of racket frame vibration received at the forearm and thus ameliorate the stress on the wrist extensor muscles, but no mechanical advantage has been demonstrated for string dampers.⁴⁹

Tennis players with TrPs in the wrist extensor muscles should avoid a “leading elbow” or an open racquet face near the time of ball impact. In addition, ball contact in the lower half of the strings should be minimized. Poor racquet mechanics can make the wrist

extensor muscles more vulnerable to potential injury.⁵⁰ Performance of the backhand stroke should be done with the wrist extended (ie, neutral alignment of the forearm and hand dorsum). In expert players, collision of the ball and racket during the backhand stroke normally occurs with the wrist extended, and the wrists move further into extension at impact.⁵¹ Expert players demonstrate greater wrist extensor activity than novice players after ball contact, consistent with the accompanying wrist extension.⁵¹ An eccentric contraction of the wrist extensor muscles throughout the stroke is observed in novice players. Because muscle overload as a result of eccentric muscle contractions is one recognized factor that leads to the development of TrPs,^{52,53} novice tennis players should be instructed to quickly release their grip tightness during backhand strokes after ball impact in order to reduce shock impact transmission to the wrist and elbow.⁵⁴

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 34-1 grossly represents the functional unit of the wrist extensor muscles, and Box 34-2 grossly represents the functional unit of the brachioradialis muscle.⁵⁵

Box 34-1 Functional unit of the ECRL, ECRB, and ECU muscles

Action	Synergists	Antagonists
Wrist extension	Extensor digitorum longus Extensor indicis Extensor pollicis longus	Flexor carpi radialis Flexor carpi ulnaris Flexor digitorum superficialis Flexor digitorum profundus
Radial deviation (ECRL)	Flexor carpi radialis	ECU Flexor carpi ulnaris
Ulnar deviation (ECU)	Flexor carpi ulnaris	ECRL ECRB Flexor carpi radialis

Box 34-2 Functional unit of the brachioradialis muscle

Action	Synergists	Antagonists
Elbow flexion	Biceps brachii Brachialis	Triceps brachii Anconeus

The ECRL muscle co-contracts with the pronator teres muscle during wrist extension movements to prevent supination of the forearm.⁴¹ During the grasping of an object, the wrist extensors act synergistically to prevent flexion of the wrist that the extrinsic finger flexors would otherwise produce.^{31–33}

3. CLINICAL PRESENTATION

Travell and Simons⁵⁵ described the referred pain patterns from TrPs in most forearm muscles that produce similar pain features of lateral epicondylalgia. Similar pain referral patterns as those described for the TrPs of the wrist extensors, with some differences, have been described in experimental pain models of lateral epicondylalgia.^{56,57} In these studies, injection of hypertonic saline^{56,58} or nerve growth factor⁵⁷ into the wrist extensor muscles (ECRB, supinator, common wrist extensor origin)⁵⁷ or into the ECRB muscle^{56,58} reproduced pain over the lateral epicondyle and spread distally into the forearm. Furthermore, infusion of hypertonic saline into latent TrPs in the brachioradialis muscle produced referred pain to the dorsum of the wrist in 35% of infusions.⁵⁹ Three clinical studies^{60–62} demonstrated that referred pain elicited by manual palpation of TrPs in the forearm musculature share similar patterns of sustained lateral elbow and forearm pain that is characteristic of people with lateral epicondylalgia.

Brachioradialis

In patients with lateral epicondylalgia, the brachioradialis muscle exhibits TrPs less often than the ECRL and ECRB muscles (50%-66%).^{60–62} The essential pain pattern of the brachioradialis muscle is into the lateral epicondyle, the radial aspect of the forearm, the wrist, and the base of the thumb (in the web space between the thumb and the index finger) (Figure 34-4). Bonica and Sola⁶⁶ illustrated the referred pain of the brachioradialis muscle to the lateral epicondyle, and Kelly⁶⁷ identified a pattern of pain and tenderness close to the elbow and a diffuse referred pain and tenderness across the dorsum of the hand.

3.2. Symptoms

Patients will typically report pain and dysfunction in the form of limited elbow, wrist, and/or hand movements. However, pain will be their primary report. The patients often describe an onset of pain that appears first in the lateral epicondyle and then spreads progressively to the wrist and hand. When the patient primarily reports lateral elbow pain, TrPs of the wrist extensors and brachioradialis muscles can be responsible for these

symptoms. If TrPs go unidentified or are not addressed, persistent chronic pain could result, leading to functional disability and high costs because of loss of productivity and increased utilization of healthcare.⁶⁸

If the ECU muscle has TrPs, the patient will typically report pain and limitations in ulnar deviation of the wrist; however, TrPs in this muscle may be responsible for atypical posterior lateral epicondyle pain. Although patients with TrPs in the forearm muscles will classically report pain as the main feature of their condition, they may also present with limited movement and/or inhibition weakness.

Pain caused by TrPs in the forearm muscles is usually manifested during loading activities of the wrist extensor muscles, such as those involving gripping or manipulating an object (eg, lifting a coffee cup, shaking hands, dressing, typing, and house work). However, some patients do not refer to a previous history of overload of the forearm extensor muscles, and the pain may have an insidious onset with no specific causal activity. Patients may also report grip weakness that can lead to objects slipping out of the hand, particularly with wrist ulnar deviation (eg, letting the head of the tennis racquet drop and lacking control when pouring milk from a carton or just before the mug reaches the lip when drinking coffee). Pain can also be felt when forceful supination or pronation is added to the grasp, as when turning a doorknob or using a screwdriver, especially when the ECU muscle is involved. When the brachioradialis muscle is involved, resisted movements of elbow flexion or thumb extension may also reproduce symptoms.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Evaluation of the cervical and thoracic spine,^{69,70} as well as neurodynamic testing of the radial nerve,⁷¹ can help to identify spinal contribution to symptoms felt in the forearm region. These tests are important even if patients do not report symptoms in the cervical or thoracic spine.⁷⁰ Subjects with lateral epicondylalgia exhibit impairments at C4 and C5 spinal levels more frequently than healthy subjects.⁷⁰

Observation of posture should focus on the elbow, wrist, and hand. Resting static posture of wrist radial deviation with extension can indicate stiffness, shortness, or overuse of the ECRL and ECRB muscles relative to the ECU muscle.⁷² Overuse of the ECU muscle may result in wrist ulnar deviation and extension at rest.⁷²

Functional assessment should include gripping tasks, along with maximal grip strength and pain-free grip strength tests using a hand-held dynamometer. This assessment allows the therapist to quantify strength deficits, inhibition weakness, and/or pain with gripping in order to evaluate treatment effects and monitor progress. In patients with lateral epicondylalgia, maximal grip strength is of limited clinical utility because it is not always impaired and because pain usually interferes with maximal or submaximal voluntary

efforts.⁷³ The pain-free grip test, which reflects the amount of force demonstrated prior to the onset of pain, is an outcome measure used as an alternative to maximal grip strength testing.⁷⁴ The test is performed with a dynamometer starting from a position of elbow extension and forearm pronation or from 90° elbow flexion and forearm in neutral rotation. From either of these two positions, the patient is asked to perform three gripping actions with 1-minute intervals between trials, and the average of these three repetitions is used for comparison between the unaffected and affected sides.⁷⁴

3.1. Referred Pain Pattern

Wrist Extensors

Pain elicited by TrPs in the ECRL muscle is referred to the lateral epicondyle and to the dorsum of the hand next to the region of the anatomic snuff box (Figure 34-3C), which is often described by the patient as “the thumb.”^{63, 64} In a study of patients with lateral epicondylalgia, ECRL active TrPs reproduced lateral epicondylar pain in 72.2% of the cases.⁶²

Figure 34-3. Referred pain patterns (dark red) from TrPs in the three primary hand extensor muscles (medium red) in the right forearm. A, Extensor carpi ulnaris muscle. B, Extensor carpi radialis brevis muscle. C, Extensor carpi radialis longus muscle.⁶⁵

ECRB TrPs project pain to the back of the hand and wrist (Figure 34-3B).⁶³ This referred pain is one of the most common myofascial sources of pain in the back of the wrist. Some studies have also found that pain referral to the lateral aspect of the elbow or the forearm, elicited by active TrPs in the ECRB muscle, reproduced the symptoms of 85% to 100% of patients with lateral epicondylalgia.^{61, 62, 65} These studies, as well as the results of the injection studies mentioned earlier,^{56–58} suggest that pain referred to the lateral epicondyle (Figure 34-3B) should also be considered as an important pattern of the ECRB muscle.^{56–58}

Pain elicited by TrPs in the ECU muscle primarily refers to the ulnar side of the dorsal aspect of the wrist (Figure 34-3A). It has also been reported that ECU TrPs sometimes refer pain to the posterior aspect of the lateral epicondyle (Figure 34-3A).⁶⁵

Figure 34-4. Referred pain pattern (dark red) from a TrP in the right brachioradialis muscle (medium red).

Symptoms reported as a consequence of TrPs in the ECU muscle are usually reproduced with resisted wrist extension with ulnar deviation.⁷⁶ Shortness of the ECU muscle is identified by increased resistance to stretch during wrist flexion and radial deviation with the forearm pronated, elbow extended, and humerus stabilized.⁷² Macdonald⁸¹ reported that passively stretching an involved ECU muscle by flexing and radially deviating the wrist caused pain, as did resisted extension with ulnar deviation of the wrist. There are no specific muscle length tests for the brachioradialis muscle reported in the literature; manual palpation of this muscle is the best examination technique for identifying a dysfunction.

Inhibition weakness of the wrist extensor muscles, which results from TrPs, may lead to

a compensatory increase in activity of the finger extensors. This neuromuscular dysfunction can manifest in the form of movement impairments in which extension of the fingers is observed during active wrist extension as a substitution strategy for wrist extensor weakness or inhibition.⁷² In addition, during contraction of the finger flexors, as with gripping or pinching, weakness in the wrist extensors may manifest as an increase in wrist flexion during the action.

Passive accessory joint motion of the radioulnar, radiohumeral, and humeroulnar joints, as well as the radiocarpal joints should be examined with and without overpressure.^{82, 83}

3.4. Trigger Point Examination

Wrist Extensors

For TrP examination of the wrist extensor muscles, the patient sits with the arm slightly abducted and supported with the forearm in a pronated position (Figure 34-5). The elbow is flexed about 30° and the patient's hand hangs down over the edge of the support surface. This position allows the clinician to identify taut bands of the different forearm muscles using either a cross-fiber flat or a cross-fiber pincer palpation (Figure 34-5).

Figure 34-5. Palpation for TrPs in the wrist extensor muscles. A, Cross-fiber pincer palpation of extensor carpi radialis longus muscle. B, Cross-fiber flat palpation of extensor carpi radialis brevis muscle. Arrow showing direction of palpation. C, Cross-fiber flat palpation of extensor carpi ulnaris muscle. Arrow shows direction of palpation.

Because the wrist extensors are superficial muscles, eliciting a local twitch response (LTR) is usually easy to obtain during clinical examination. A LTR from cross-fiber pincer palpation of the ECRL muscle normally produces strong radial deviation of the hand and some extension at the wrist (Figure 34-5A). The prevalence of active TrPs in the ECRL muscle in patients with lateral epicondylalgia ranges between 70% and 95%.^{60–62}

The ECRB muscle is a relatively thin muscle that lies almost parallel to the axis of the forearm, together with the finger extensors. Trigger points in the ECRB muscle are usually located in the muscle mass on the ulnar side of the brachioradialis muscle, distal to those in the ECRL muscle. The muscle may be examined by cross-fiber flat palpation against the radius to elicit its LTR, which produces hand extension with slight radial deviation at the wrist (Figure 34-5B). Active TrPs in the ECRB muscle range between 65% and almost 100% in patients with lateral epicondylalgia.^{60–62}

The ECU muscle can be located in the dorsal ulnar side of the forearm. The patient is asked to perform wrist extension with ulnar deviation or thumb abduction⁴⁵ to make the muscle more prominent. Cross-fiber flat palpation is applied just distal to the lateral epicondyle and medially from the sharp edge of the ulna toward the dorsal surface of the forearm (Figure 34-3A). If the clinician is able to elicit a LTR with cross-fiber flat palpation, it produces extension and ulnar deviation of the wrist (Figure 34-5C), although a LTR in this muscle is difficult to elicit.

Resisted movement testing of the wrist extensors should be performed to identify which muscles may be involved and if there are associated neurologic deficits. Symptoms reported as a consequence of TrPs in the wrist extensor muscles are usually reproduced with the resisted wrist extension test (Cozen test), with the resisted middle finger test (Maudsley's test), or by having the patient grip an object. These tests are also used for the clinical diagnosis of lateral epicondylalgia. Maudsley's test, tenderness with palpation of the radial tunnel (anterior to the neck of the radius), and reproduction of symptoms with resisted supination are, together, considered clinical signs indicating radial tunnel syndrome.⁷⁵

When performing resisted wrist extension, modification of the elbow position can be helpful to differentiate between the ECRL and ECRB muscles as the source of symptoms. Symptoms reproduced with resisted wrist extension with the elbow flexed bias the ECRB muscle, whereas painful wrist extension with the elbow extended biases the ECRL muscle.⁷⁶ It is important to note that reproduction of familiar pain by resisted extension of the wrist, index, or middle finger; pain upon gripping; and pain with palpation of the lateral epicondyle are considered the cardinal physical signs for diagnosing lateral epicondylalgia.^{77,78}

Passive physiologic range of motion should be tested at the wrist, both with the elbow extended and flexed. Length deficit of the ECRL muscle may be a contributing factor to limited elbow extension range of motion when the wrist is flexed. Therefore, elbow extension range of motion should be tested with and without a stretch on the ECRL muscle.⁷⁴ Maximum stretch on the ECRL and ECRB muscles occurs with combined passive wrist flexion, forearm pronation, and elbow extension, with the humerus stabilized

in neutral rotation.⁷⁹ Length deficits of the ECRL and ECRB muscles result in wrist extension and radial deviation range of motion limitations when the arm is pronated with the elbow extended and the humerus stabilized in neutral.⁷⁵ Takasaki et al⁸⁰ investigated effective positions for elongating the ECRB and ECRL muscles and found that the maximal strain on those muscles was obtained with elbow extension, forearm pronation, and wrist flexion with ulnar deviation. These combined positions should not only be utilized to assess muscle length but also be subsequently used for stretching the ECRL and ECRB muscles,⁸⁰ if found to have length deficits because of adaptive shortening or TrPs.

Brachioradialis

The brachioradialis muscle is the most superficial muscle at the lateral elbow. It is a relatively thin muscle that is located immediately overlying and parallel to the ECRL muscle. Cross-fiber pincer palpation is preferred for examining the brachioradialis muscle because the clinician can encircle the muscle between the thumb and fingers and separate it from the underlying ECRL and ECRB muscles. For palpation of TrPs in the brachioradialis muscle, the patient sits comfortably with the forearm resting on a padded armrest, forearm pronated or in neutral and the elbow slightly flexed (Figure 34-6). The patient is asked to flex the elbow against resistance with the forearm in a neutral position. In this position, and especially when the elbow flexion is resisted at 90° of flexion, the brachioradialis muscle becomes more pronounced and it is easy for the clinician to palpate it using a pincer grasp.

Figure 34-6. Cross-fiber pincer palpation for TrPs in the brachioradialis muscle.

Mora-Relucio et al⁸⁴ evaluated the interexaminer reliability of three clinicians (two experienced and one novice) on TrP location (at a distance <1.5 cm) and classification

(relevant, nonrelevant, absent) in the wrist extensor musculature. Data showed 81.73% of agreement on TrP classification and 85.58% on TrP location between the two experienced clinicians for the ECRB muscle. The agreement on TrP classification between experienced and inexperienced clinicians was 54.81% and 51.92%, respectively, for the ECRB muscle, and the agreement between experienced and inexperienced clinicians on TrP location was 54.81% and 60.58%, respectively, for the ECRB muscle. Findings from this study also demonstrate that experienced clinicians were able to reliably identify and palpate TrPs in the extensor digitorum muscle. The level of interexaminer agreement was significantly better with experienced clinicians as compared to inexperienced clinicians.⁸⁴

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the extensor muscle group or brachioradialis muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁸⁵ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points are activated in the ECRL, ECRB, and brachioradialis muscles by repetitive forceful grasping. The larger the object being grasped, and the greater the amount of ulnar deviation required of the hand, the more likely the muscles are to develop TrPs. This theory means that TrPs in the wrist extensor and brachioradialis muscles are common in tennis players and in individuals working in professions requiring handling of heavy loads or tools, forceful gripping or pronation/supination manual tasks with a combination of force, repetition, and awkward postures. Adopting awkward postures such as a non-neutral wrist position during work activity (eg, gripping with a more flexed wrist position)⁷³ can produce high eccentric loads and overelongation of the wrist extensor muscles, thus activating and/or perpetuating TrPs in these muscles. The optimal wrist posture for maximal grip force in healthy adults is reported in slight wrist extension.⁸⁶

Other examples of activities that can activate or perpetuate TrPs in these muscles are: dressing, house work, racquet sports, weeding with a trowel, extensive handshaking, scraping ice off a windshield, ironing of clothes, and repetitive frisbee-throwing. Carrying heavy objects, poor posture while at the computer keyboard, or playing musical instruments can also act as activating or perpetuating activities. Chen et al⁸⁷ found significant decrease in pain pressure thresholds over latent TrPs in the forearm muscles of piano students after only 20 minutes of playing.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.⁹⁸ Therefore, musculature in the referred pain areas for each muscle should also be considered.

Trigger points frequently occur in the ECRL, ECRB, and brachioradialis muscles; involvement of one of these muscles is likely to be associated with TrPs in the extensor digitorum and supinator muscles. Trigger points are rarely observed in the ECU muscle as a single muscle syndrome and typically occur with at least one TrP in the extensor digitorum muscle.

Trigger points in the brachioradialis muscle often develop in association with TrPs in the supinator and ECRL muscles. Involvement then spreads to the long extensors of the fingers, especially to the middle and ring fingers. The distal lateral end of the medial head of the triceps brachii muscle, proximal to the lateral epicondyle, may also develop associated TrPs. These TrPs refer pain to the lateral epicondyle as well.

Trigger points located in remote muscles referring pain to the forearm region can favor the development of associated TrPs in the forearm muscles. For instance, dry needling of infraspinatus TrPs inhibited the activity of TrPs situated in its zone of pain referral (eg, ECRL muscle).⁹⁸ Similarly, one dry needling session of active and latent TrPs of the infraspinatus muscle was followed by a reduction of pain intensity and irritability of latent TrPs located in the ECRB muscle in older adults with nonspecific shoulder pain.⁹⁹ This remote influence seems to occur in a reciprocal direction as well. Tsai et al¹⁰⁰ showed that dry needling of the ECRL muscle could reduce the irritability of proximal TrPs located in the upper trapezius muscle. Trigger points in the scalene or supraspinatus muscles may induce associated TrPs in the ECRL, ECRB, and ECU muscles. Trigger points in the serratus posterior superior muscle can also induce TrPs in the ECU muscle.¹⁰¹

Similarly, patients can develop TrPs bilaterally in the same musculature, that is, a “mirror” affectation. This phenomenon has been explored in individuals with lateral epicondylalgia because latent TrPs in the ECRB and ECRL muscles were found in a similar percentage in the unaffected forearm in patients with strictly unilateral elbow symptoms.⁶¹

4.3. Associated Pathology

Clinical entities producing lateral elbow pain include ECRB tendinopathy, true tennis elbow, local arthritis at the elbow,¹⁰² radiocapitellar pathology (ie, synovial plica at the humeroradial joint),^{103–105} radial tunnel syndrome,^{75,106} posterior interosseous nerve entrapment,¹⁰⁷ cervical radicular pain or radiculopathy,¹⁰⁸ posterolateral rotatory instability,¹⁰⁹ and nonspecific arm pain,¹¹⁰ which is defined as diffuse forearm pain not associated with any particular structure.

When pain or paresthesia is felt distally in the upper extremity and/or the brachium, along with diffuse arm pain or concomitant neck pain, the clinician should suspect the presence of cervical radicular pain, radiculopathy, or radial nerve entrapment.^{78,111,112}

Local tendon pathology at the tendinous insertion of the ECRB muscle is one of the underlying pathophysiologic mechanisms in lateral epicondylalgia.^{111,112} The most common site of focal degeneration in lateral epicondylalgia has been reported in the deep and anterior fibers of the proximal insertion of the ECRB tendon.^{113–115} These pathologic changes were considered by several authors as the primary candidate for the pathologic basis

of lateral epicondylalgia.^{113, 114}

Pain mechanism changes (eg, central sensitization)^{58, 61, 116–121} and motor system impairments^{111, 112} also contribute to the clinical picture of lateral epicondylalgia and elbow pain. Several neuromuscular impairments have been demonstrated in people with lateral epicondylalgia including reductions in pain-free grip force,⁷⁴ weakness in the wrist extensors with compensatory increased activity in the finger extensors,^{89, 122} morphologic changes in the ECRB muscle,¹²³ widespread muscle weakness in the affected limb,^{89, 122} and motor control deficits.⁷³

The ECU muscle, which is seldom required to support a load against gravity, develops TrPs to a lesser extent than the other wrist extensors. Its involvement is usually secondary to gross trauma, such as fracture of the ulna, or as a sequela of frozen shoulder syndrome, in which most of the shoulder muscles and many of the elbow muscles develop TrPs.

Motor control dysfunctions may also activate or perpetuate TrPs in the forearm muscles. For instance, abnormal activation patterns of forearm extensor muscles and poor posture of the upper limb have been reported in people with lateral epicondylalgia.⁵⁰ In particular, during the performance of a backhand tennis stroke, tennis players with pain developed higher levels of electrical activity of the wrist extensors at ball impact when compared to asymptomatic subjects. In addition, the ECRB muscle of tennis players with lateral epicondylalgia was less active in the early preparatory phase prior to ball impact, reflecting impaired stability at the wrist, whereas activity was greater at ball impact. Individuals with lateral epicondylalgia showed a “leading elbow” posture during the backhand at ball impact in which the wrist was extended more in individuals with lateral epicondylalgia than the tennis players without lateral epicondylalgia.⁵⁰ Reduced activity of the ECRL and ECRB muscles was demonstrated in subjects with lateral epicondylalgia during isometric wrist extension⁸⁸ and gripping tasks.⁸⁹ The relationship between these neuromuscular imbalances and development of TrPs in the forearm muscles needs to be investigated further.

Joint dysfunctions in the elbow or wrist may also perpetuate TrPs of the forearm muscles. For instance, restriction of scaphoid mobility at the wrist in a volar direction may limit wrist extension and thus impart muscle overload in the forearm muscles. In this regard, a scaphoid thrust manipulation technique has been successfully used in the treatment of lateral epicondylalgia.⁹⁰

Different counterforce braces^{91–94} and taping techniques⁹⁵ applied to the forearm region can be helpful to reduce the lateral elbow pain provoked by TrPs of the wrist extensors and brachioradialis muscles. Because results may be similar with different types of braces, the choice will depend on factors such as patient preference, comfort, and cost.⁹⁴ If a forearm support band is used, it may be most effective for reducing strain in the ECRB muscle when applied at a force of 40 to 50 mm Hg and used during light-duty activities.⁹⁶ Moreover, the strain on the ECRB muscle origin is less when the forearm support band is applied at four-fifths the distance from the wrist to the elbow.⁹⁷

In addition, triangular fibrocartilage complex tear, distal radioulnar joint injury or

instability, and ECU tendinopathy should be considered as potential sources of symptoms in the dorsum of the ulnar distal wrist.

The pain referral elicited by TrPs to the dorsum of the hand and wrist, especially in the region of the base of the thumb, may easily be mistaken for tenosynovitis (de Quervain's disease), which presents with similar symptoms.¹²⁴ In both conditions, the pain is aggravated by either loading or stretching the involved tendons and muscles.

When symptoms are located at the base of the thumb, other causes of pain besides TrPs and de Quervain's disease should be taken into consideration such as carpometacarpal entrapment of the superficial radial nerve (Wartenberg syndrome).

Dorsal wrist pain may be caused by pathologies including intersection syndrome, Kienbock's disease, or wrist instability (eg, scapholunate dissociation). Details about key features and clinical examination procedures for identifying all these clinical syndromes can be found elsewhere.^{112, 125}

Unfortunately, many of the above-mentioned diagnostic labels lack accepted definitions and diagnostic criteria. For instance, nonspecific arm pain is a diagnosis often reached by exclusion of other specific conditions. However, there are some clues from the clinical history and physical examination that can orient clinicians for effective diagnosis. Clicking at the elbow, loss of control, or difficulty with pushing up with the forearm supinated may indicate posterolateral instability of the radial head.¹¹² Reproduction of lateral elbow pain during manual palpation and/or active, passive, or combined movements of the cervical spine, concomitant neck pain, or diffuse arm pain or paresthesias should raise suspicion of radicular or referred pain.¹¹² Patients with posterior interosseous nerve entrapment usually report pain over the dorsal aspect of the forearm and exhibit muscle weakness of the finger and thumb extensors without sensory loss.¹²⁶

5. CORRECTIVE ACTIONS

The patient with TrPs in the radial wrist extensors should avoid forceful and repeated activity with the wrist flexed and ulnarly deviated. It may be helpful to adapt certain activities and provide adequate rest and recovery periods during prolonged and repetitive tasks as follows: liquid should be poured from a container by rotating the arm at the shoulder joint, instead of by ulnarly deviating or twisting at the wrist, or by providing support to the bottom of the container with the unaffected hand. The patient should learn to avoid activities that can aggravate brachioradialis TrPs, such as digging with a trowel, prolonged shaking of hands, and playing tennis with a racquet that is too heavy. If the patient is an avid tennis or golf player, he/she should seek professional consultation for a movement analysis of their swing and for any equipment modifications.
